*"To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH.

THURSDAY, SEPTEMBER 3, 1914.

OUR RARER BIRDS.

Field-studies of Some Rarer British Birds. By John Walpole-Bond. Pp. x + 305. (London: Witherby and Co., 1914.) Price 7*s.* 6*d.* net.

THE scope of the volume before us is well indicated by its title. Mr. Bond, indeed, keeps us from first to last in the open air observing the habits of the birds and discovering the secrets of their nests. Now the author is at home in the south-east of England, now he visits well-loved haunts in Wales; or, again, he wanders further afield—to the wild coast of Ireland, to the fastnesses of the Central Highlands, or to the moors of Orkney. It is evident that Mr. Bond writes about no mere holiday excursions, but that he has been able to give much time to field ornithology, and has travelled far and wide throughout our islands in its pursuit.

The birds which have been chosen for treatment do not all in like degree deserve the title "rare." A few, indeed, are merely rather restricted in their distribution—either from natural cause or owing to human persecution. But although the needless destruction of many of our most interesting birds comes in for just censure, there is a brighter side to the picture: the golden eagle is well protected in Scotland, our buzzard population is estimated at more than four hundred and fifty pairs; the raven and the peregrine hold their own in the remoter districts; the hobby is more numerous than is generally supposed; the decrease of the chough is not attributed to human agencies; while the gadwall is an *addition* to our native avifauna.

In these days of nature photography, very excellent in its way, it is something of a relief to find a bird-book that is able to stand on the merits of text alone. But at the same time we become more exacting as to literary form, and therein discover our author's failing. The extraordinary number of parenthetical and other interpolated clauses gives a disjointed and inconsequent effect to a style already loose. One has the impression, indeed, that a horde of new details has been added at the last moment without any attempt at recasting the sentences. This is a grave fault, for it does much to mar the reader's pleasure while constantly "side-tracking" his interest. Nevertheless, Mr. Bond has much to tell that few know, but that many will gladly learn.

SCIENCE AND THE FARMER.

(1) *A Pilgrimage of British Farming,* 1910–1912. By A. D. Hall. Reprinted by permission from the *Times.* Pp. xiii + 452. (London: John Murray, 1913.) Price 5*s.* net.

(2) *Soils and Crops; With Soils Treated in Reference to Crop Production.* By Prof. T. F. Hunt and Prof. C. W. Burkett. Pp. xiii + 541. (New York: Orange Judd Co.; London: Kegan Paul, Trench, Trübner and Co., 1913.) Price 7*s.* 6*d.* net.

(3) *Manures and Fertilisers.* By Prof. H. J. Wheeler. Pp. xxi + 389. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 7*s.* net.

(1) "TO see himself as others see him" is nowadays very much the fate of the man who lives in the country and gets his living by agriculture. He has only to open his morning paper to find some speech or article by some prominent person setting forth the good or bad conditions under which he and his labourers live, and propounding some remedy for the evils described.

Probably more has been written about the country during the last twelve months than about the cities, and there still continues a steady outpour of material describing the state of British agriculture in general, and the conditions of life in the country in particular. It appears, therefore, that the city dweller is much interested in the subject, and apparently much of what is written appeals to him or the shrewd publisher would not publish it. The drawback of a good deal of it is, unfortunately, that the countryman rarely recognises the descriptions, and is driven to wonder how they ever came to be written.

Mr. Hall's book stands out in sharp contrast with all this; it is written by one who knows what he is talking about, and presents a very faithful picture of British agriculture and rural conditions. The tour covered practically all the good farming districts of Great Britain and Ireland, and it brings out the high specialisation which is now becoming so characteristic of British farming. Some farms indeed can only be compared with factories, so closely specialised is the work, and so intense the production. It is not too much to say that no account has yet been printed which gives so good a description of the farming of this country, and it was a very happy inspiration indeed that led Mr. Hall and his two companions, Mr. Beaven and Prof. Wood, to go round the country in a car and put on record what was seen. The last tour of the sort was conducted by Caird in 1850–51 and a comparison of the two books shows very clearly that enormous strides have been made since that date. The economic conditions have altered considerably, but the farmer has succeeded in adapting himself to them, and has developed a system which enables him to produce a great amount of material from his land at a reasonable profit to himself.

Of course, the picture is not uniformly bright; losses still go on on the farm that ought to be checked; farmers generally cannot obtain credit and are often indebted to dealers, so that they are unable to make any complaint when unsatisfactory goods are supplied, or to take advantage of the Acts of Parliament which have been passed for their benefit; there is much room for cooperation. The labourer, too, is not so well off as he might be. He is, of course, in a much better position than is commonly made out, and he can always, if he wants, move off to the Colonies and set up farming on his own account. In general, however, he is at least as well off as the labourer in the town. Again, the system of rural education is not well adapted to the needs of the rural community. Fortunately, however, in all these directions serious efforts are being made for improvement, and we can look forward with confidence to the future.

It is impossible in a short space to discuss the various facts that Mr. Hall has recorded; perhaps the most characteristic feature noted is the close association of sheep with British farming systems: the way in which crops are grown simply for sheep to eat on the land so that the soil may be fertilised and compacted without having recourse to implements. It is quite a common thing to grow one or two fodder crops to be consumed in this manner, and to follow these with corn crops. Thus the food materials purchased for sheep help to fertilise the soil and also to keep up the supply of organic matter. It is much less common to find the farmer depending entirely on artificial manures.

The tendency to specialisation in agricultural production brings into prominence the difficulties inherent in dealing with crops, soil fertility, diseases, etc.; it makes the farmer more observant and more ready to seek scientific assistance. The skilled hop grower is far more interested in the life-history of the aphis or the mildew than is the small general farmer in any account of the rust of wheat. With specialisation in agriculture, therefore, comes the opportunity to the man of science; it thus tends to bring about much closer cooperation between the agricultural and scientific adviser than was possible some years ago.

(2) The second book on our list was written by Dean Hunt and Prof. Burkett and deals with the special conditions of the United States; it is an attempt to bring into one volume sufficient material for pupils between the ages of fourteen and eighteen. It deals not only with soils and manures, but also with crops, including maize, oats, wheat, barley, and a variety of others, while chapters are added on the insect pests and diseases, and on the methods of improvement of crops. Both the authors have had very great experience in teaching; Dean Hunt, now of California, saw service at the State College, Pennsylvania, and elsewhere, whilst Prof. Burkett is well known as the editor of the *American Agriculturist*, and was also director of the Kansas Agricultural Experiment Station.

The arrangement is in some respects novel; the first chapter deals with food required to grow plants and includes accounts of salt, sugar, starch, fat, protein, besides the usual potassium salts, phosphates, and nitrogen compounds. Then the student passes on to a study of the different types of soil, and the characteristics of soils and fertilisers. As is usual in American books a liberal use is made of illustrations, whilst there is a good supply of practical exer

cises. Altogether the book is one that the teacher may use with great advantage and in the certainty of getting much help in devising useful courses for his classes.

(3) The third book is by Prof. Wheeler who was long director of the Agricultural Experiment Station of Rhode Island, and then became chemical expert to the American Agricultural Chemical Company. His book deals exclusively with manures and fertilisers, and is therefore more specialised than the volume just referred to. A very interesting account is given of the subject, indeed, we know of no American publication that deals better with it. The author has rightly made liberal use of the admirable series of investigations conducted at Rhode Island during the term of his directorship, and in particular goes very fully into the question of liming. Some remarkable observations were begun in 1890 at Rhode Island and it was found that sulphate of ammonia was highly toxic on certain soils, even in the first season of its application. Experiments soon showed that this effect was due to the production of acid conditions in the soil, which could be corrected by sodium carbonate, potassium carbonate, calcium carbonate, but not by chlorides or sulphates. Liming was therefore indicated as the proper method of dealing with the trouble. These observations appear to have been the first that were made on the subject; and they lead to a very complete study of the method of correcting acidity arising from the use of ammonium sulphate.

A further interesting feature is the prominence given to the use of seaweed as a manure. This subject attracts periodical attention, but very little progress has been made in the direction of utilisation, in spite of the enormous possibilities it seems to present. And yet the amount of fertilising material thrown up on our shores in the course of a year is enormous.

A pleasant feature of the book is the great prominence given to European work, Rothamsted experiments in particular coming in for a great amount of attention.

The book is very interesting and will be of considerable value to teachers and students of the subject. E. J. Russell.

OUR BOOKSHELF.

Morocco the Piquant, or Life in Sunset Land. By G. E. Holt. Pp. xi+242. (London: Wm. Heinemann, 1914.) Price 6*s*. net.

Mr. Holt, who seems to have held for about six years the post of American vice- and deputy-consul-general at Tangier, enjoyed facilities of exploring the interior of Morocco denied to European diplomatists who exercise a more active and less disinterested influence on the affairs of that distracted country. The note of his book is the strange conflict of Oriental and Western culture so close to Europe. He gives in naïve fashion and with a breezy style a sketch of the cosmopolitan population of Tangier, where he is reminded everywhere of the Arabian Nights. He was able to visit that strange Alsatia within ten miles of Tangier, held by the turbulent Angheras; he interviewed the bandit Raisuli, whom the Spaniards, it is said, are now ready to take into their service, at his refuge Arzila.

Perhaps the best part of the book is the chapter describing the Djinn, or evil spirits, the primitive animistic belief over which Islam is only a veneer, and his visit to a peasant household, an industrious farmer and his capable wife, good specimens of the fine material in the population, and capable of regenerating this harassed land if only it were subjected to a decently efficient Government. An energetic observer, with his American ideas of hustle and the superiority of Western industrialism is not the best authority on a primitive culture like that of Morocco, and his observations do not go far beneath the surface. But the facts of the present system and the notes on popular superstitions will interest students of politics and folklore. In face of the recent defeat of the Senoussi by the Italians, we can scarcely accept the prediction that Europe is menaced by a Mohammedan rising in North Africa.

Elementary Logic. By A. Sidgwick. Pp. x+250. (Cambridge University Press, 1914.) Price 3*s*. 6*d*. net.

An excellent manual, combining an adequate account of the old logic with a good exposition of modern developments. As becomes a logician, Mr. Sidgwick divides his book into parts and smaller sections, with admirable system and sequence. Part i. deals with the syllogism in all its forms, also with induction and fallacies, in which matters the author follows Mill for the most part. Interesting illustrations are chosen, and the treatment renders the text as readable as circumstances allow. It is admittedly impossible to make "Barbara" and her associates look anything but dull, however they are dressed up; but logic (as Browning said of his own poetry) is "not a substitute for dominoes," so the student will no doubt struggle through. Mr. Sidgwick gets the dull part disposed of as quickly as thoroughness will allow. In Part ii. we reach the more interesting and "live" part. The modern point of view is adopted, and formal logic is shown to establish only validity and not truth, because there is always something assumed. Further, classes are man-made, not nature-made; and, as we cannot say all that can be said about *S*, *S* may be in one class in certain of its relations, and in another when others of its aspects are being considered. Briefly, truth is relative to purpose. And proof is never coercive. The new logical method is modest. It looks forward with confidence, however, to a "great increase in the

effectiveness of an appeal to facts against the verbalism which springs from uncritical acceptance of the abstract laws of thought."

Natural Sines to every Second of Arc, and Eight places of Decimals. Computed by E. Gifford. (Manchester: Abel Heywood and Son, 1914.) Pp. 543. Price 15*s*.

ANY practical means of assisting the computer is to be welcomed, and this volume of natural sines to every second of arc, and to eight places of decimals, will be sure to have a considerable practical value, even to those who use machines. The sines to 10″ are those from the "Opus Palatinum of Rheticus" (published 1596); the sines to 1″ were interpolated by the Thomas calculating machine being copied to ten places. The table is arranged like Chambers' log tables, the figures to the right of the seconds being prefixed to each of the sets in the same horizontal line, except when the sets are dotted, when the first four digits are taken from the line below. Considering the laborious nature of, and the accuracy required in the construction of these tables, the compiler is to be heartily congratulated on the successful completion of the task.

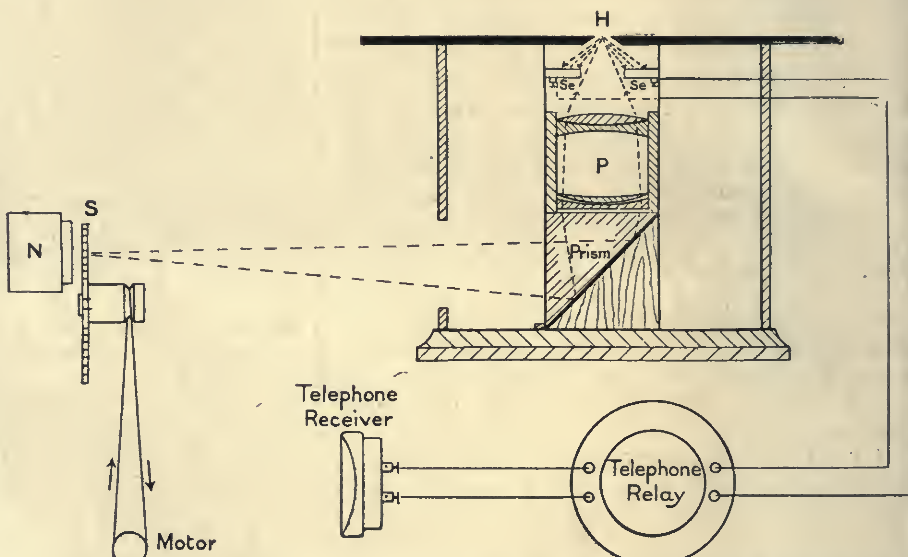
THE TYPE-READING OPTOPHONE.

ANY instrument designed for translating optical into acoustic effects, or light into sound, and thus to some extent substituting the ear for the eye, may be appropriately termed an "optophone." The intermediate link is either heat or electric current, and in view of the fact that a current of a few thousandths of a microampere is audible in the best modern telephones (if intermittent), one would naturally use an electrical rather than a thermal link. This is done in the various forms of "optophone" devised by the author since the Optical Convention of 1912.

The latest of these, described before the Royal Society on May 28, and shown at the conversazione of the society on June 16, is designed with the object of enabling blind persons to "read" ordinary letterpress by means of the ear. The accompanying illustration of the optical arrangement is reproduced from the Royal Society paper by permission of the council.

An optical system throws the image of a glowing Nernst filament upon the printed paper, laid face downwards on a suitably perforated desk. This image is broken up into a series of seven or eight luminous dots, flashing with different musical frequencies, by means of a rotating siren disc placed immediately in front of the Nernst filament. Some light-sensitive preparation, preferably of selenium, is placed close to the type so as to receive whatever light is diffusely reflected by it. The size of the image is made to fit the size of type to be read, and a sensitive telephone is put in series with the selenium and a battery, or with one of S. G. Brown's telephone relays.

It has been found possible to obtain a "readable" sound from type of the ordinary newspaper size. The straight black stem of a letter produces silence, and a curved letter, such as S, produces in its passage a set of gradually changing notes which are characteristic of the letter, and cannot be mistaken even after only a few minutes' practice. To learn the entire alphabet in this way should be a matter of a few weeks or months,



Type-reading optophone. N, Nernst lamp; S, rotating siren disc; P, portrait lens, throwing image of line of intermittent dots on the printed matter placed face downwards at H; Se, selenium preparation receiving diffusely reflected light.

but the amount of practice required will vary very greatly from one person to another, as only a "musical" ear can readily detect the omission of certain notes from a given chord. Given an adequate alignment and line-changing mechanism, there is no reason why, with sufficient practice, ear-reading should not be almost as rapid as the ordinary reading at sight.

The choice of type is, of course, unlimited. There is no arbitrary element in the determination of the sounds required to represent the various letters, as each type will automatically produce its own characteristic sounds. With considerable practice, a blind person, thus trained to allocate certain notes to certain positions, should be able to construct "instinctively" a visual (or tactile) image of any new or unfamiliar letterpress type at the first hearing.

E. E. FOURNIER D'ALBE.

NOTES.

THE president of the Board of Trade has appointed committee to consider and advise as to the best means of obtaining for the use of British industry sufficient supplies of chemical products, colours, and dyestuffs of kinds hitherto largely imported from countries with which we are at present at war. The committee is constituted as follows:—Lord Haldane (chairman), Dr. George T. Beilby, F.R.S., Dr. J. J. Dobbie, F.R.S., Mr. David Howard, Mr. Ivan Levinstein, Prof. Raphael Meldola, F.R.S., Mr. Max Muspratt, Prof. W. H. Perkin, F.R.S., Mr. Milton Sharp, Sir Arthur J. Tedder, Mr. Joseph Turner, Mr. T. Tyrer, with Mr. John Anderson, of the National Health Insurance Commission, and a representative of the Board of Trade. The secretary of the committee is Mr. F. Gossling (of the Patent Office), to whom all communications should be addressed at the Commercial Intelligence Branch of the Board of Trade, 73 Basinghall Street, E.C.

THE closing of the Baltic ports and shortage of labour in the Bordeaux district of France have greatly reduced the normal supply of pitprops. As the provision of an adequate supply of mining timber is of great importance, the Board of Agriculture and Fisheries, in cooperation with the English Forestry Association, are taking steps to stimulate the marketing of home-grown timber. The timbers most in demand are larch, Scotch pine, and spruce of 3-in. diameter and upwards at the small end, but small hardwood timbers, such as oak, coppice, and beech are used to some extent. The standard lengths of pitprops differ in the various districts. Owners of extensive woods who may have timber which they consider suitable for this purpose but are in doubt as to the best method of marketing it or of obtaining it with least damage to the future welfare of their plantations, are invited to communicate at once with the secretary of the Board of Agriculture and Fisheries, or with the secretary, English Forestry Association, Farnham Common, Slough, Buckinghamshire.

THE present crisis will affect the electrical industry on account of the shortage of carbons for arc lighting. There is only one works manufacturing carbons in this country, the great majority of carbons having been imported from Germany and Austria. France also exports carbons to England, and there is a small factory in Spain. A limited supply may be available from Spain, but no imports are, of course, available from Germany and Austria, and the French factory is situated in the heart of the fighting at Nancy. The only carbon factory in America cannot do more than supply American wants, even if it is able to do this, as America imports carbons largely from Germany. Public lighting as well as the electrical industry will suffer, owing to the neglect and refusal of electric lighting authorities to support the enterprise which twelve years ago started manufacturing carbons in this country. The Admiralty and certain other Government departments which have recognised for some time past the necessity of having a source of supply independent of foreign carbons are now reaping the reward of their foresight in being able to obtain their supplies in this country. The present output of the carbon works in question is not sufficient to supply more than one-tenth of the carbons required in this country, but a very different state of affairs would have been the case if the carbon works had been properly supported in the past, for, in this case, the works would by now have been at least three or four times their present size. We can only hope that sufficient support will be given to British-made carbons in the future to allow of the present works being extended sufficiently to meet at least all public lighting demands for this country.

WHILE continuing their excavations in the Piltdown gravel last week, Mr. Charles Dawson and Dr. A. Smith Woodward met with a second portion of a molar tooth of Mastodon larger and more characteristic than the fragment originally described. The new specimen agrees well with the teeth of *Mastodon arvernensis* found in the Red Crag of Suffolk, but it is merely a waterworn hindmost ridge, and is evidently a derived fossil of earlier date than the deposition of the Piltdown gravel itself.

Two important additions have been made to the exhibited collection of Ichthyosaurians in the British Museum (Natural History). A nearly complete skeleton of Ophthalmosaurus, collected with great skill by Mr. Alfred N. Leeds from the Oxford Clay of Peterborough, has been mounted on an iron framework with all the bones approximately in their original relative positions. It is thus possible to realise the shape and proportions of this reptile during life much more readily than can be done by an examination of the crushed specimens in slabs of rock. The closeness of the ribs immediately behind the shoulder-girdle is especially interesting. The vertebral column is stoutest at the hinder end of the abdominal region, and the downward prolongation in the lower lobe of the tail-fin is gracefully curved. The paddles must have been very flexible, with much cartilage between the ossifications, and the hind paddles are so small as to be almost rudimentary. A slab of Upper Lias from Holzmaden, Würtemberg, shows a complete skeleton of *Ichthyosaurus acutirostris* with the surrounding soft parts as a bituminous impression on the rock. The specimen is one of the finest examples of Mr. Bernhard Hauff's work in preparing such fossils. The triangular dorsal fin and the vertically extended tail-fin are clearly seen, and there are several structures in the dorsal region of the trunk which still need interpretation.

As already announced, in consequence of the war the Comité des Forges de France has been obliged to cancel all arrangements for an autumn meeting of the Iron and Steel Institute in France this year. In the circumstances, the council of the institute has decided that it would be advisable to postpone for the present the organisation of any alternative arrangements for an autumn meeting for the reading and discussion of papers. A number of papers have been submitted with a view to their presentation at the meeting which was to have been held at Paris, and the council proposes to print in the usual way advance

copies of those papers approved for publication and to invite discussion thereon by correspondence. It is expected that the copies will be ready for issue about the second week in September.

THE following resolution has been passed by the Chadwick trustees.—That in view of the immense importance of encouraging in every way the promotion of careful sanitary organisation in the naval and military services during the present campaign, the Chadwick trustees have resolved under the powers conferred upon them under the scheme they administer to announce their intention to award at the close of this year the Chadwick gold medal and 50*l*. each to the naval and military medical officer respectively in the British service who shall have distinguished himself most in promoting the health of the men in the Navy and the Army. The nomination for such presentations to be, as provided by the terms of the trust, by the directors-general of the naval and military medical services respectively.

IN vol. viii., No. 6, of the *Philippine Journal of Science*, Mr. R. B. Bean discusses certain types among the inland tribes of Luzon and Mindanao. He postulates three distinct migrations from Europe: one from Europe direct, without mingling with intervening peoples, as represented by the almost pure European types in the heart of Luzon and Mindanao; one by way of India, in which the types are the Indian and the so-called Malay; and one from Arabia and North Africa, the Mohammedan of history. There is also evidence among the Ilongots of another European element migrating through Siberia, possibly through China, and also from Japan. The Australoid type may antedate the Negritos, it may have resulted from them by crossing with other types, or it may have been brought in with the other types in the mingling migrations of the Europeans.

IN their report on the ethnozoology of the Tewa Indians of New Mexico by Messrs. J. Henderson and I. P. Harrington, published as Bulletin 56 of the Bureau of American Ethnology, the writers give a striking picture of the changes in the environment and fauna of the region due to the advent of the white man. The land was originally well grassed, and supported a large head of varied game. On the introduction of great herds of cattle from Texas, the situation rapidly changed. The grasses disappeared under their tongues and hoofs, many species of vegetation vanished, the surface became denuded of humus, and the underlying stones and gravels were exposed. In one pueblo in Arizona bones of thirty-seven species of animals were discovered in the rubbish heaps; it is not probable that five of these could now be collected. The writers also show that the current belief which attributes to the Indians an almost magical power of discriminating and naming the varieties of plants and animals is erroneous. They do distinguish species more closely than the average white man without training in botany or zoology; but they naturally fail to recognise the more minute differences, many of which are microscopic.

A NUMBER of striking photographs of the norther[n] or Lado, race of the white rhinoceros (*Rhinocero[s] simus cottoni*) serve to illustrate the second instalme[nt] of notes on African big game, by Mr. Russell Robert[s] in the August number of *Wild Life*, this portion al[so] concluding the account of the African elephant.

THE *Egyptian Gazette* of August 12 announces t[he] arrival at the Gizeh Zoological Gardens of a co[n]signment of 118 animals from the Sudan, for the mo[st] part presented by English and native donors, offic[ial] and otherwise. The series includes thirty-seven mam[]mals, sixty-six birds, and fifteen reptiles, representin[g] forty species and races. Among the first is a very monkey (*Cercopithecus pygerythrus*) from the Mo[] galla district, a species previously unknown north [of] East Africa. The menagerie at Gizeh has also r[e]ceived a Mediterranean seal (*Monachus albiventer*), [a] species formerly abundant on the coasts of the s[ea] from which it takes its name, but now unknown [on] the Egyptian coast west of Alexandria, although [a] few still remain in Tunisian waters, while a stragg[ler] is from time to time taken in the Adriatic.

IN a useful article by Mr. R. C. Mo[s]man in *Symons's Meteorological Magazine* [for] August on the renewal of Antarctic explo[ra]tion and research, it is pointed out that t[he] interest in this subject is shown by the fact that t[he] plans of four specified expeditions have been bef[ore] the public for some time. A map has been prepar[ed] giving the positions where meteorological and oth[er] observations have been made, and the number [of] years over which they extend. This map shows th[at] "only over one-third of the S. Polar area south [of] 60° S., and extending in one instance only so far [as] 78° 30′ S., have we even a general knowledge of [its] climatic features throughout the year." A consid[er]able part of the available data relates to summer co[n]ditions only, and, as the author remarks, it is [a] matter for congratulation that in the near future [we] may look forward to a substantial addition to [our] knowledge of the meteorology of those regions.

THE report of the Meteorological Committee for [the] year ended March 31 shows that considerable chan[ges] have taken place, owing to a liberal increase of [the] Parliamentary grant. Among the more import[ant] items may be mentioned (1) the institution of a gr[ade] of junior "professional" assistants (with Univers[ity] qualifications) for meteorological and geo-phys[ical] work. (2) The satisfactory termination of nego[tia]tions with the Scottish Meteorological Society; [one] of the several advantages is the inclusion in one p[ub]lication of available climatological data for all pa[rts] of the British Islands. (3) A notable improvement [in] the reconstruction of the central ("Kew") obser[va]tory, after the departure of the assistants belong[ing] to the National Physical Laboratory, and a consi[der]able addition to the instrumental equipment. (4) [The] establishment of a "weather station" at Falmou[th], in conjunction with the Royal Cornwall Polytech[nic] Society, in place of the photographic recording [ob]servatory, for the purpose of special researches [in] weather prediction, and the investigation of the up[per]

It is satisfactory to note some improvement in rate of transmission of wireless reports; a wireless eiving apparatus has been installed at the office for ssages forwarded from the Eiffel Tower. Comisons of the weather forecasts and storm warning egrams for the United Kingdom with subsequent ather show that the percentage successes have been y satisfactory. As an appendix to Dr. Shaw's eresting report is reprinted a circular containing ful particulars relating to the international units measurement recently adopted

Some interesting notes on the changes occurring ring the manufacture of tea are given in a paper by r. S. Sawamura in the Bulletin of the Imperial ntral Agricultural Experiment Station of Japan. In e manufacture of green tea the oxidising enzymes the leaf are killed by steaming, but it is essential at the steaming should not be too far prolonged, herwise other enzymes, which play a part in the oduction of the aroma, are also destroyed, and the bsequent quality is impaired. The effect of rolling e leaves is to increase the easy solubility of the nstituents which give quality to the infusion, and t the same time desiccation of the leaves is also ccelerated owing to juice being pressed out from the nterior of the cells. Experiments are also described howing the effect of different temperatures during the firing" of the leaves.

An interesting contribution to the study of the ormation of hydrogen cyanide in plants is contained in paper by Prof. A. Jorissen in the Bulletin of the Royal Academy of Belgium (1914, p. 130). It is shown that citric acid in presence of oxidising agents and a trace of a nitrite gives rise to hydrogen cyanide, probably owing to the action of the nitrite on acetonedicarboxylic acid, which is the first product of the oxidation. In dilute solution and in sunlight it is shown that small quantities of ferrous or ferric salts can effect the preliminary oxidation of the citric acid, even ferrous bicarbonate being sufficient for the purpose. Citric acid is widely diffused in plants, and light, which brings about its oxidation in presence of traces of iron, is also well known to favour cyanogenesis. It is probable therefore that the above described synthesis of hydrogen cyanide is one which is realised in the actual plant in many instances.

The success of the "Tee" process for the production of white salt from rock-salt gives occasion for an illustrated article in *Engineering* for August 21, descriptive of the works now in operation at Carrickfergus, in Ireland. In this process the rock-salt is fed into a gas-fired furnace, where it melts and runs from the furnace into a "bath." The bath contains a slagging chamber, on the floor of which the greater proportion of the impurities is deposited; the molten salt then reaches other two chambers in the bath, each containing a 3 in. wrought iron pipe with a number of $\frac{1}{8}$ in. holes through which compressed air at a pressure of from 8 to 10 lb. per sq. in. is blown. The state of agitation into which this throws the molten salt results in a further deposit of slag in both chambers. The molten salt then passes slowly through a settling-chamber, thence to a reservoir, and finally through two tap-holes to the rotary pans. The rotary pans crystallise the molten salt in one operation by means of stationary rakes, the latter performing the function of agitating the rapidly-cooling molten salt in such a manner as to crystallise it, ready for the market, in various grades, and sized according to requirements. The total rated capacity of the three furnaces at Carrickfergus is 70 tons of refined salt in 24 hours. The whole operation is continuous, the salt being deposited in a finished state ready for the market within half-an-hour of coming out of the mine.

The Cambridge University Press has added two further volumes to its series of Cambridge County Geographies, which when complete will cover the whole of the British Isles. One volume is on Glamorganshire, and is written by Mr. J. H. Wade; the other deals with Durham, and is by Mr. W. J. Weston. As in other cases, the books are brightly written, and give a readable account of the geography and geology of the areas, followed by a description of their economic resources and history. The maps, illustrations, and diagrams will maintain the high standard reached in previous volumes.

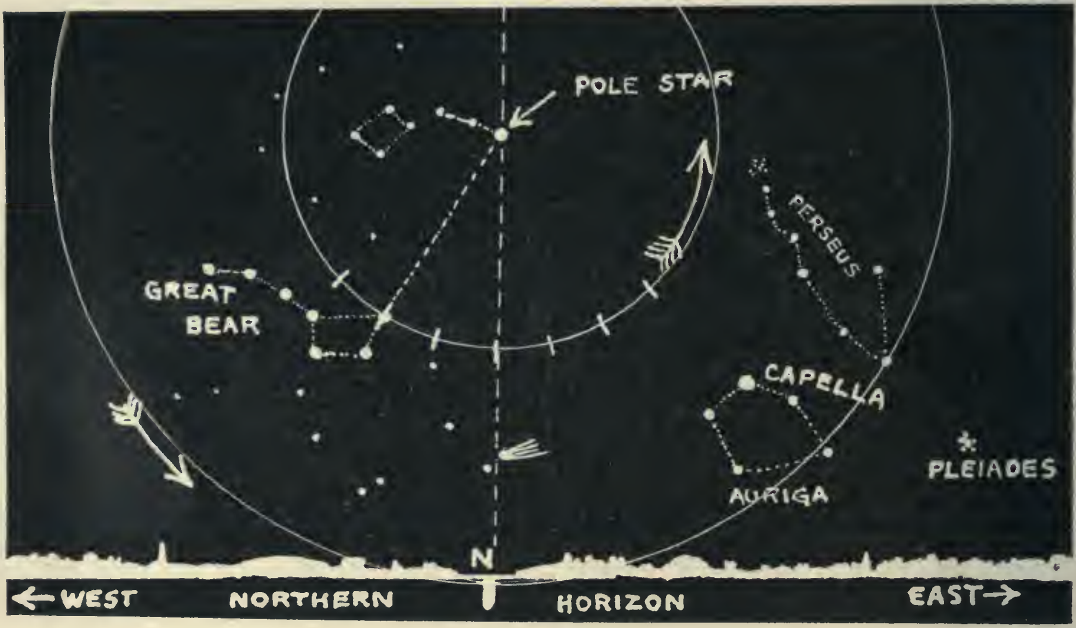
OUR ASTRONOMICAL COLUMN.

The Recent Perseid Shower of Meteors.—Mr. Denning reports that many observations from various stations have come to hand, and that the results are of a singularly interesting character. Though the shower was rather noteworthy for its brilliant meteors it was not exceptional as regards numbers. The fine weather which prevailed afforded some recompense for the moonlight. More than thirty bright meteors were observed at two stations or more, and their heights, radiants, and velocities have been found. The maximum occurred on August 11, but there were a few belated Perseids as late as August 20. One feature of the recent shower was that a number of fine meteors were not Perseids, but members of one or other of the many minor radiants which abound at this time of the year. The most conspicuous of these was in Lyra at $280^\circ+44^\circ$, and there were others at $292^\circ+51^\circ$, $312^\circ+61^\circ$, $354^\circ+77^\circ$, $309^\circ+6^\circ$, and $74^\circ+33^\circ$.

The last three showers were seen during the latter part of the month. The Aquilids at $309^\circ+6^\circ$ appear to form a new display, which, if it has been previously visible, seems to have eluded detection. The meteors are bright and move slowly in rather long flights. The display in Auriga at $74^\circ+33^\circ$ forms a pretty active display of swift conspicuous meteors leaving bright streaks. This shower was also seen on the morning of August 28, 1881, by Mr. Denning. He describes the meteors as being of very great velocity, and often having very extended flights across the firmament. A brilliant member of the stream was recorded on August 28 last at 10h. 25m. p.m., moving along a path of 84° from a few degrees N. of α Arietis, almost to the planet Jupiter. It was also seen from Kent, where its path was estimated as 100° long. It passed from over Kent to the English Channel about seventy-five miles S. of Portland Bill. Path, 182 miles, and velocity forty-five miles a second.

Comet 1913*f* (Delavan).—The accompanying chart is intended for the use of those who desire an easy means of finding Delavan's comet, which is now a

conspicuous object in the night sky. In this chart the observer is supposed to be looking due north, *i.e.* towards the pole star, the star being easily found by the direction of the two pointers in the Great Bear. If a vertical line be imagined drawn through the pole star towards the horizon, then this line will approximately pass through the comet at about ten o'clock in the evening. While the comet has not a great altitude, it is well above the northern horizon, as shown in the chart. To the left of the comet is the constellation of the Great Bear, and well to the right (eastwards) is the constellation of Auriga with the bright star Capella. It should not be forgotten that, owing to the rotation of the earth, the constellations have an apparent motion round the pole star, as indicated by the arrows marked near the circles in the chart. During the night, therefore, the stars and the comet, as one faces northward, describe concentric circles round the pole star, and consequently the stars *under* Polaris move from left to right. The diagram thus clearly indicates that the later the comet is observed, the higher above the horizon it will be situated, and the *best* time to observe it is between two o'clock and four o'clock in the morning. The divided part of the smaller circle in the diagram shows approximately the hourly apparent movement of the stars.



The comet is a naked eye object, and is a fine sight as seen even with a pair of field glasses or a small telescope. In the earlier part of the night, when the comet is low down, the tail is nearly horizontal, stretching out towards the east. As the morning approaches, the tail becomes more inclined, the head then being at a lower altitude than the tail. The comet has a very dense, almost stellar nucleus and a considerable length of tail. On August 26 the nucleus was estimated (visually) as being about magnitude five, and the tail about one degree long, but on August 28 the tail was judged to be equal to about four lunar diameters, *i.e.* about two degrees in length, and the nucleus of magnitude three. There is little doubt that this object is being closely followed at all observatories. Some good photographs of the spectrum of the nucleus were secured during the early mornings of last week at the Hill Observatory, Sidmouth, with a prismatic camera of 12 in. aperture and a 20° prism.

RADIAL MOTION IN SUNSPOTS.—The subject of the radial motion in sunspots is referred to in three communications to the July number (vol. xi., No. 1) of the *Astrophysical Journal*. The first is contributed by Prof. W. H. Julius, and the position he takes up is "to defend the attacked position which is by no means so weak as he represents it" in the criticism of Mr. St. John of the anomalous dispersion theory in explaining the observed phenomena. Space does not permit one even to summarise Prof. Julius' conclusions, but it may be stated that the paper covers thirty-two pages, and concludes with eleven paragraphs of summary. The communications by Messrs. Evershed and St. John deal with the question of the limits of the radial motion. Mr. St. John's investigations indicated that the usual course of the displaced lines over spots showed no sharp break, and the displacement did not suddenly cease at the periphery of the penumbra, but the line gradually returned to its normal course. Mr. Evershed's view is that there is an appreciable break or jolt in the lines at the points where they pass from the penumbra on to the surrounding photosphere. The communications suggest that these different views are to some extent one of degree, and possibly due to the differences caused by the instrumental equipment of these investigators. Mr. St. John hopes to utilise the next maximum period of sunspots to make a special examination of this question, and a programme has already been planned.

THE AUSTRALIAN MEETING OF THE BRITISH ASSOCIATION.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY PROF. SIR THOMAS H. HOLLAND, K.C.I.E., D.Sc., F.R.S., PRESIDENT OF THE SECTION.

EXACTLY eighty-three years from the day of our arrival at Sydney, Edward Suess was born in London. Thus the day, as much as the circumstances of our meeting so far from home, serves to remind us of one who was great enough to recognise the fact that geo-

logical evidence from any part of the world has the same value as that obtained in the little continent which has been the most prolific in the products of nomenclature and the most productive in text-books.

Since the days of Charles Lyell no geologist has been so conspicuously successful in analysing the accumulated mass of evidence, in bringing together the essential facts from all hands, and in compensating for the local excesses of literature. Only those of us who, by long absence from Europe, have felt the full disadvantages of having to express our thoughts in alien terminology can appreciate the real value of Suess's great work. His death since our last meeting makes a conspicuous mark in the history of geological science.

A meeting of the British Association in Australia brings home forcibly to the members of Section C the fact that British Imperial geology is really "the science of the earth"; partly for this reason one feels inclined to get outside the science and take a survey of some of its suburbs. Not many of them have been left untraversed by my distinguished predecessors in this chair; but there has been of recent years a tendency to avoid the inner earth, which has rightly been described as "the inalienable playground of the imagination," and consequently, therefore, common land to the geologist as well as the geodesist, physicist, and mathematician.

The geologist who looks below the purely superficial phenomena of the crust is generally regarded as straying beyond his province; but the desire to see the birth certificate of some of the strange and often unacceptable "causes" which the mathematical physicist offers us is a pardonable form of curiosity. Our ideas regarding intra-telluric conditions are even proving to be of economic value, one of the most recent and unexpected results of the kind being that just established by Baron von Eötvös in Hungary,[1] whose predictions now bid fair to outstrip those of the "diviner"! Having noticed the low gravity values over the great cores of rock-salt in the Transylvanian "Schlier," he finds similar defects of gravity in the same region over certain of the Sarmatian and Pontian domes, which probably owe their shape to subterranean salt-plugs and are now found to be great storehouses of natural gas, which, with or without liquid petroleum, is commonly found with the saline "Mediterranean" facies of the Upper Tertiary in Eastern Europe. Baron von Eötvös also finds that on the eastern margin of the Great Hungarian Plain, where the younger Tertiary beds are completely concealed by a mantle of alluvium, mud-volcanoes and gas-springs are sometimes found in areas of marked gravity defect, and some of these are now also being drilled for natural gas.

When our ideas of the state of affairs below the surface thus begin to yield economic results, there is hope that they are at last steadying down, becoming more settled, and indeed more "scientific." It may not be unprofitable, therefore, to review some of the advances recently made in developing theoretical conceptions regarding the interior of the earth that are of direct importance to geologists. In undertaking this review I am conscious of the fact that I shall be traversing ground that is generally familiar to all, and much of it the special property of specialists whose views I hesitate to summarise and should not dare to criticise. As the author of the "Ingoldsby Legends" said of the only story that Mrs. Peters would allow her husband to finish, "The subject, I fear me, is not over new, but will remind my friends—

"Of something better they have seen before."

[1] *Comptes rendus*, XVIIème Conf. de l'Assoc. Géodés. Internat. Hamburg, 1912, pp. 427, 437.

The intensity and quantity of polemical literature on scientific problems frequently varies inversely as the number of direct observations on which the discussions are based: the number and variety of theories concerning a subject thus often form a coefficient of our ignorance. Beyond the superficial observations, direct and indirect, made by geologists, not extending below about one two-hundredth of the earth's radius, we have to trust to the deductions of mathematicians for our ideas regarding the interior of the earth; and they have provided us successively with every permutation and combination possible of the three physical states of matter—solid, liquid, and gaseous.

Starting, say, two centuries back with the astronomer Halley, geologists were presented with a globe of which the shell rotated at a rate different from that of its core. In more recent times this idea has been revived by Sir F. J. Evans (1878) to account for the secular variations in the declination of the magnetic needle.

Clairault's celebrated theorem (1743), on which Laplace based the most long-lived among many cosmogonies, gave us a globe of molten matter surrounded by a solid crust. Hopkins demanded a globe solid to the core, and, though his arguments were considered to be unsound, his conclusions have been revived on other grounds; while the high rigidity of the earth as a body has been maintained by Lord Kelvin, Sir George Darwin, Prof. Newcomb, Dr. Rudski, and especially by the recent observations of Dr. O. Hecker, supplemented by the mathematical reasoning of Prof. A. E. H. Love. Hennessy (1886), however, concluded that the astronomical demands could be satisfied by the old-fashioned molten earth in which the heavier substances conformed to the equatorial belt.

As long ago as 1858 Herbert Spencer suggested that, on account of its temperature being probably above the critical temperature of known elements, the centre of the earth is possibly gaseous. Late in the seventies Dr. Ritter revived the idea of a gaseous core surrounded by a solid crust, and this was modified in 1900 by the Swedish philosopher, Svante Arrhenius, whose globe with a solid crust, liquid substratum, and gaseous core is now a favourite among some geologists.

Wiechert (1897) supposed that the core of the earth, some 5,000 kilometres in radius, is composed mostly of iron with a density of 7·8, while this is surrounded by a shell of lithoidal material having a density of about 3·0 to 3·4; and this great contrast in density is about that which distinguishes the iron meteorites generally from those of the stony class. Arrhenius also assumes that iron forms the main part of the central three-quarters, and he shows that this distribution of substance may still be consistent with his theory of a gaseous core; indeed, he not only imagines that the whole of the iron nucleus is gaseous, but also most of the siliceous shell, for he leaves only 5 per cent. of the radius as the depth of the solid and liquid shells combined.

But the variety of ideas does not end with theories on the present constitution of the globe. Poisson required the process of solidification to begin from the centre and to progress outwards, while other mathematicians had been happy with the Leibnitzian *consistentior status* as the first external slaggy crust. Since the days of Laplace all naturalists have been forced to accept the idea of a solar system formed by the cooling and condensation of a spheroidal gaseous nebula; and all except those geologists who have vainly searched for traces of the primeval crust have been happy in this belief.

Recently, however, Dr. F. R. Moulton and Prof. T. C. Chamberlin in America have brought together arguments from different points of view to construct

the solar system by the aggregation of innumerable small bodies, "planetesimals," which have gathered into knots to form the planets. Thus, the earth is supposed to have grown gradually by the accretion of meteoritic matter, and even now, although the process has nearly ceased, it receives much meteoritic material from outside.

With the Chamberlin-Moulton theory there must have been a time when the gravity of the earth was insufficient to hold an atmosphere of any but the heavier gases, such as carbon dioxide; later, the earth became heavy enough to retain oxygen, then nitrogen, water-vapour, and helium; while even now it may not be sufficiently attractive to prevent the light and agile molecule of hydrogen from flying off into space. With the growth of the young globe, the compression towards the centre produced heat enough to melt the accumulated fragments of meteoritic matter, and the molten material thus formed welled out at the surface. Such volcanic action is supposed to have predominated at the surface until an appreciable atmosphere was formed, and became charged with water, when the now familiar processes of weathering, erosion, and deposition produced the film of "rust" which geologists know as sedimentary rocks.

With this last addition to the variegated array of theories about the physical condition of the earth and about its genealogy, the scientific world began again to settle down into serenity, comforted by the happy feeling that all at any rate agree in regarding the earth as a gradually cooling body, with many millions of years still before it. Then came the discovery of radium, and, with it at first, an assurance that geologists were justified in claiming a long past, to be followed by a longer future than the most optimistic philosopher had dared before to assume with our apparently limited store of earth-heat. Now, however, Prof. Joly warns us that if the deeper parts of the globe contain anything near the proportion of radio-active bodies found by him in the superficial rocks, we may even be tending in the other direction; that, instead of a peaceful cooling, our descendants may have to face a catastrophic heating; the now inconspicuous little body known as the earth may indeed yet become famous through the universe as a new star.[2]

To add to the variety of ideas regarding the present state of the earth's interior, Prof. Schwarz, of Grahamstown,[3] concludes that our volcanic phenomena can be accounted for on the assumption that the main mass of the earth below a superficial layer is cold and solid throughout, being composed, like the meteorites, largely of unaltered ferromagnesian silicates and iron.

Thus, we see, whole fleets of hypotheses have been launched on this sea of controversy: some of the craft have been decoyed by the cipher-signals of the mathematician; some have foundered after bombardment by the heavy missiles classically reserved for use by militant geologists; others, though built in the dockyard of physicists, have suffered from the spontaneous combustion set up by an inadvertent shipment of radium. Still, some of these hypotheses are yet apparently seaworthy, and it may not be unprofitable to compare them with recently acquired data.

The nearest approach to actual observation with regard to the state of the earth's interior has been obtained by the seismograph, designed to record the movements of seismic waves at great distances from the disturbing earthquake. Some of the waves sent forth from an earthquake-centre travel through the earth, and some travel around by the superficial crust, the former reaching the distant seismograph before the latter. The seismograph, by its record of the waves that travel *through* the earth, has thus given a certain amount of information regarding the state of the earth's interior which R. D. Oldham aptly regards as analogous to that given by the spectroscope[4] with regard to the inaccessible atmosphere of the sun.

The existence of two groups of earthquake-waves —those passing through, and those passing near the surface around the earth—has long been recognised; but R. D. Oldham[5] has shown that the waves passing through the earth are of two kinds, travelling at two different speeds.

The record on the distant seismograph thus shows three well-marked phases: the first phase, due to waves of compression passing through the earth's interior; the second phase, due to waves of distortion,[6] also passing through the earth's interior; and the third phase, recorded by the waves which pass around the arc along the superficial crust.

The third phase is always recorded at a time after the occurrence of the shock proportional to the arcual distance of the recording seismograph from the earthquake centre, the records of several large earthquakes showing an average speed for the waves of about three kilometres a second. The rates of propagation of the waves giving the first and second phases are both much greater than of those forming the third phase; and up to an arcual distance of about 120° from the earthquake's centre the rate of their propagation increases with the distance. It is thus assumed that the waves giving rise to the first and second phases in each distant seismographic record, by following approximately along the chord of the arc between the place of origin and the instrument, pass through deeper layers of the earth when the seismograph is farther away, the material at greater depths being presumably more elastic as well as denser.

But Oldham[7] has shown that when the seismograph is as much as 150° from the earthquake centre there is a remarkable decrease in the mean apparent rate of propagation of the waves giving the second phase in the record, from more than six to about four and a half kilometres a second. There is also a drop, although not nearly so marked, in the apparent speed of the waves of the first phase when transmitted to a seismograph 150° or more distant from the earthquake origin. Oldham concludes that this decrease of apparent rate for waves travelling through the earth to places much more than 120° distant is due to their passing into a central core, four-tenths of the radius in thickness, composed of matter which transmits the waves at a markedly slow speed. Thus the earthquake waves which emerge at a distance not greater than 120° from their origin do not enter this central core, while those which pass into the earth to a greater depth than six-tenths of the radius are supposed to be refracted on entering, and again on leaving, the postulated core, in which the rate of transmission of an elastic wave of distortion is very much slower than in the main mass of the earth around. In consequence of the refraction of these waves on passing through the central core, places situated at about 140° from an earthquake origin should be in partial shadow, due to the great dispersion of the distortional waves, and the few records made so far by seismographs thus situated with regard to great

[4] In his presidential address to the Geological Society of London in 1909, Prof. W. J. Sollas (Proc. Geol. Soc., 1909, p lxxxvii.) credits H. Benndorf (Mitth. Geol. Gesellsch. Wien, I., 1908, 336) with this pretty analogy, but Oldham has the precedence by just two years (*cf.* Quart. Journ. Geol. Soc., vol. lxii., 1906, p. 456).

[5] Phil. Trans., Ser. A., vol. cxciv. (1900), pp. 135–74.

[6] There is more complete agreement regarding the fact that two distinct sets of waves give rise to the so-called preliminary tremors indicated by a seismographic record than about the nature of the waves. Confer. R. D. Oldham, Phil. Trans., *loc. cit.*, and O. Fisher, Proc. Cambr. Phil. Soc., vol. xii., pp. 354–61.

[7] Quart. Journ. Geol. Soc., vol. lxii., pp. 456–475 (1906).

earthquakes show that there is either no, or at most a doubtful, record for the second phase, which is known to be due to the so-called distortional waves.

Oldham's deductions are based confessedly on a small number of earthquake records—he considered fourteen examples only—but the conclusions based on a small number of trustworthy records, from which variations due to the different methods of marking the phases are eliminated, are more trustworthy than those for which there are imperfect distant records as well as doubts regarding the exact times of the disturbances. If these observations, however, be confirmed by further records, we are justified in assuming that below the heterogeneous crust there is a thick shell of elastic material, fairly homogeneous to about six-tenths of the radius, surrounding a central core, four-tenths in thickness, which possesses physical properties utterly unlike those of the outer layers; for in this core the "distortional" waves are either damped completely or are transmitted at very much lower speeds than in the shell.

One cannot consider this interesting inference from the seismographic data without being reminded of the contention of Ritter, Arrhenius, and Wilde regarding the possibility of a persistent gaseous core still above the critical temperature of the substances of which it is composed. According to Ritter,[8] the gaseous core is surrounded by a solid shell. Dr. Wilde[9] postulates the existence of a liquid substratum and a gaseous core within a solid crust, the two outer shells having a thickness that is "not very considerable." Arrhenius assumes from purely physical considerations that the solid crust is only about twenty-five miles thick, that below this it is possibly in a molten condition for about a hundred and fifty miles, and that the rest is a gas largely composed of iron under a pressure so great that its compressibility is not much less than that of steel.

The whole of these conclusions, being based on assumptions regarding the physical properties of matter under conditions of temperature and pressure that are well beyond those of actual experience, must be put on a plane of science well below that occupied by the investigations initiated by Oldham, who opens up a line of research in which, as said before, the seismograph may justifiably be compared with the spectroscope as an instrument for observing some inaccessible regions of nature.

The mathematician apparently finds it just as easy to prove that the earth is solid throughout as to show by extrapolation from known physical values that it must be largely gaseous. As Huxley said in his presidential address to the Geological Society in 1869, the mathematical mill is a mill which grinds you stuff of any degree of fineness, but, nevertheless, it can grind only what is put into it; and the seismograph thus offers a new source of substantial grist. Now that it is fairly certain that some of the earthquake-waves pass through the deeper parts of the earth, it is obvious that a fruitful development of science will follow successful efforts to introduce precision in recording, and uniformity of expression in reading, seismographic records.

Oldham[10] has pointed out another way in which analysis of seismographic records may lead to information regarding intra-telluric conditions by comparing the records of waves that pass under the oceanic depressions with those that are sub-continental for the whole or most of their paths. By comparing the records in Europe of the Colombian earthquake of January 31, 1906, with those of the San Francisco earthquake in the following April, there was a greater interval noticed between the first and second phases of the Californian earthquake—an interval greater than can be accounted for by mere difference of distance between the origin of the shock and the recording instruments. The seismic waves which passed from Colombia to Europe must have travelled under the broadest and deepest part of the North Atlantic basin, whilst those from California ran under the continent of North America, crossed the North Atlantic not far south of Iceland, and approached Europe from the north-west, the wave paths throughout being under continents or the continental shelf of the North Atlantic. There is thus suggested some difference between the elastic conditions of the sub-oceanic and the sub-continental parts of the crust—a difference which, judging by the particular instances discussed, may extend to a depth of one-quarter of the radius, but is not noticeable in the waves which penetrate to one-third of the radius below the surface.

Obviously these data must be multiplied many times before they can be regarded as a trustworthy index to a natural law; but it is significant that this indication of a difference between the physical nature of the sub-oceanic and sub-continental parts of the crust is in rough correspondence with the conclusions previously suggested on quite other grounds.

In his presidential address to the Geographical Section of the British Association at Dover in 1899, the late Sir John Murray directed attention to the chemical differentiation which has been going on between the continents and the oceans since the processes of weathering and denudation commenced. By these processes the more siliceous and specifically lighter constituents are left behind on the continents, while the heavier bases are carried out to the ocean. It is to this process that Prof. T. C. Chamberlin[11] also ascribes the origin of the depressions in which the oceanic waters have accumulated. As a corollary of the planetesimal theory, Chamberlin assumes that water began to be forced out of the porous surface blocks of the accumulated meteoritic material when the earth's radius was between 1500 and 1800 miles shorter than it is now; at that time pools of water began to be formed on the surface, and the atmosphere, just commencing its work, began the operation of leaching the heavier bases out of the highlands. Growth of the world proceeded by the infall of planetesimals, and while those meteorities that fell on the highlands became deprived of their soluble bases, those that fell into the young ocean were merely buried unaltered. Thus, by the time the earth reached its present size its crust under the oceanic depressions must have developed a chemical composition differing from that under the continents. According to the deduction suggested by Oldham from the seismographic records, there is a noticeable difference in the sub-oceanic areas to depths of between 1000 and 1300 miles—a layer in which the followers of Chamberlin's theory might reasonably expect some physical expression of the partially developed chemical differentiation.

The occurrence of denser material below the oceans has, of course, long been assumed from the deflection of the plumb-line, and was accepted by Pratt for his theory of compensation, as well as by Dutton as a wide expression of the theory of isostasy. Cham-

[9] "On the Causes of the Phenomena of Terrestrial Magnetism," Pamphlet, 1890, p. 2. The idea that the Earth's magnetism is due to the electricity generated by the friction between the shell and the core, rotating with a different motion, was suggested by Dr. Wilde in 1902 (Mem. Manch. Lit. and Phil. Soc., vol. xlvi., part iv. p. 8, 1902). A similar suggestion based also on Halley's conception of a separately rotating inner core was made previously by Sir F. J. Evans in 1878 ("Remarkable Changes in the Earth's Magnetism," NATURE, vol. xviii. p. 80).

[10] Quart. Journ. Geol. Soc, vol. lxiii, 344–350 (1907).

berlin[12] thus explains the general prevalence of basic lavas in oceanic volcanoes.

The apparent heterogeneity indicated in the outer shell of the earth to depths of 1000 miles is naturally in conflict with the assumption that from thirty miles or so down the materials are in a liquid condition; at any rate, the idea conflicts with Fisher's extreme conception of the liquid substratum, in which the fluidity is supposed to be sufficient for the production of convection currents, upwards beneath the oceanic depressions, spreading horizontally towards the continents, and thence downwards to complete the circuit.

The idea that changes of azimuth and of latitude may be brought about by the sliding of the earth's crust over its core has been put forward more than once to account for the climatic changes of past geological ages—the occurrence of temperate or even warm climates on parts of the crust now within the polar circles, and glacial conditions at the sea-level in countries like India, Australia, Africa, and South America, which are now far from the polar ice-sheets, and in some cases near or within the tropics. Prof. E. Koken, of Tübingen,[13] in an elaborate memoir entitled "Indisches Perm und die Permische Eiszeit," attributes the idea of a sliding crust to Mr. R. D. Oldham; but a similar suggestion was put forward by the late Sir John Evans twenty years before the publication of Mr. Oldham's paper,[14] and when the theory was restated in more precise form, ten years later,[15] it was subjected to mathematical criticism by J. F. Twisden, E. Hill, and O. Fisher.[16]

Sir John Evans suggested that this movement of the crust was inevitable as a consequence of the moulding of the orographical features and consequent redistribution of weights; but Twisden came to the conclusion that the rearrangement of the great inequalities on the earth's surface would be insufficient to produce any appreciable sliding of the order required to make material differences in the climate of any place.

Oldham,[17] who was writing at the time in the field in India and thus away from literature, put forward the idea in 1886 as an independent thought, and made use of Fisher's new theory regarding the existence of a fluid stratum between the solid crust and the supposed solid core to account for the shifting of places relative to the axis of rotation from the equatorial region even to the polar circles. Oldham directed attention to the recorded small changes of latitude at certain observatories and to the probable changes of azimuth in the Pyramids of Egypt—evidences of a kind which have since been greatly enlarged by the work of Sir Norman Lockyer and others.

The movements assumed to have taken place during the human period are of course small; and to project from them changes as great as the transfer of lands from the polar circle to the tropics has the objection that characterises a surveyor's use of "unfavourable" triangles in a trigonometrical survey. Before admitting, therefore, that these small changes of latitude and of azimuth may be classed with the palæoglacialists' evidence as data of the same kind, though so utterly different in magnitude, it is desirable briefly to examine the geological evidence regarding past ice-ages in extra-polar areas.

From the records of ancient glaciations we might omit those of the pre-Cambrian rocks of North Ontario, and the pre-Upper Cambrian of Norway, as these areas are nearer the poles than many places which were certainly covered with ice-sheets during the youngest, or often so-called Great, Ice Age. But besides these we have evidence of glaciation in the Cambrian or possibly pre-Cambrian rocks of South Australia at a latitude of 35° or less; in South Africa there were two or more distinct glacial periods before Lower Devonian times in slightly lower latitudes; while in China similar records are found among rocks of the Lower Cambrian, or possibly of older age, at a latitude of 31° N.

The glacial boulder-beds found at the base of our great coal-bearing system in India belong to the same stratigraphical horizon as the glacial beds found in South Africa, certain parts of Australia, and in parts of Brazil and São Paulo near or within the southern tropic.

These glacial beds are often referred to in geological literature as Permo-Carboniferous in age; but Prof. Koken regarded the formation in India as Permian. Other valuations of palæontological evidence, similar to that relied on by Prof. Koken, place these beds at a distinctly lower horizon in the European stratigraphical scale, and recent work by officers of the Geological Survey of India in Kashmir tends to confirm this latter view; we now regard the base of our great coal-bearing system in India—the horizon of the glacial-boulder-beds—as not much, if at all, younger than the Upper Coal Measures of Britain.[18] The precise age of the horizon is not very important for our present consideration: the important point is that in or near Upper Carboniferous times a widespread glaciation occurred throughout the area now occupied by India, Australia, and South Africa. The records of this great glaciation are thus found stretching northwards beyond the northern as well as southwards beyond the southern tropic.

Now, on the assumption that the cold climate in this region was due to a movement of the crust over the nucleus, Prof. Koken has produced an elaborate map of the World, showing the distribution of land and sea during the period, with the directions of ocean-currents and of ice-sheets. The Permian South Pole he places at the point of intersection of the present 20th parallel S. and 80th meridian E.—that is, at a point in the Indian Ocean about equidistant from the glaciated regions of India, Australia, and South Africa. The Permian North Pole is thus forced to take up its position in the centre of Mexico, while the Equator strikes through Russia, Italy, West Africa, down through the South Atlantic and round by Fiji to Vladivostock.

The very precision of this map reduces the theory on which it is based to a condition of unstable equilibrium. If glacial conditions were developed in India, Australia, and South Africa by a 70° movement of the crust, were the movements to and from its assumed position in Permian times so rapid that the glaciation of these widely separated areas appear to be geologically contemporaneous? If such movements had occurred, instead of evidences of glaciation over a wide area at the *same* period, we ought rather to find that the glaciation in each of the widely separated points occurred during distinctly *different* geological periods.

But that is not the only weak spot in the evidence. The Permian (or Permo-Carboniferous) glaciation of Australia took place on the east and south-east of the continent as well as in Western Australia, and

18 H. H. Hayden, Rec. Geol. Surv. Ind., vol. xxxvi., p. 23, 1907.

the eastern ice-sheets would thus have been active within 30° of Prof. Koken's Permian equator. There are still three other serious pieces of colour-discord in this picture. In the State of São Paulo—that is, within Koken's "Permian" tropics—Dr. Orville Derby has described beds which strikingly recall the features of the Upper Palæozoic glacial beds of India and South Africa. It is possible that these are due to the work of glaciers at a high level; but, since the publication of Prof. Koken's memoir, other occurrences of the kind have been described by Dr. I. C. White in different parts of Brazil, and there is a general correspondence between the phenomena in South America and those in the formations of the same age in the Indian, Australian, and African regions.

Then, too, if we accept this expression of the physical geography during Upper Palæozoic times, we must carefully explain away the suspicious breccias and brockrams which have been regarded by many geologists as evidences of a cold climate during Permian times in the Urals, the Thüringerwald, the English midland and northern counties, Devonshire and Armagh—places that would lie on or near Koken's "Permian" equator. Finally, we find the hypothetical Permian North Pole in a locality which has failed to produce any signs of glaciation.

To attempt a discussion of the explanations offered to account for the great Upper Palæozoic glaciation would lead us far from the present theme. The question is raised merely to show that the phenomena are not consistent with the supposed movement of a solid shell over a solid core assisted by an intermediate molten lubricant. Geologists may be compelled to hand back the theory of a molten substratum to the mathematicians and physicists for further repair; but it does not necessarily follow that a foundation theory is unsound merely because it has been overloaded beyond its compressive strength.

The extraordinarily great distances between the areas that show signs of glaciation in Permo-Carboniferous times form a serious stumbling-block to most of the explanations which have hitherto been offered. One is almost tempted in despair even to ask if it is not possible that these fragments of the old Gondwana continent are now more widely separated from one another than they were in Upper Palæozoic times. It is a bold suggestion indeed that one can safely put aside as absurd in geomorphology. There is nothing else apparently left for us but the assumption of a general refrigeration.

The idea of the greater inequalities of the globe being in approximately static equilibrium has been recognised for many years: it was expressed by Babbage and Herschel; it was included in Archdeacon Pratt's theory of compensation; and it was accepted by Fisher as one of the fundamental facts on which his theory of mountain structure rested. But in 1889 Captain C. E. Dutton presented the idea "in a modified form, in a new dress, and in greater detail"; he gave the idea orthodox baptism and a name, which seems to be necessary for the respectable life of any scientific theory. "For the condition of equilibrium of figure, to which gravitation tends to reduce a planetary body, irrespective of whether it be homogeneous or not," Dutton [19] proposed "the name *isostasy*." The corresponding adjective would be isostatic—the state of balance between the ups and downs on the earth.

For a long time geologists were forced to content themselves with the conclusion that the folding of strata is the result of the crust collapsing on a cooling and shrinking core; but Fisher pointed out that the amount of radial shrinking could not account even for the present great surface inequalities of the lithosphere, without regard to the enormous lateral shortening indicated by the folds in great mountain regions, some of which, like the Himalayan folds, were formed at a late date in the earth's history, folds which in date and direction have no genetic relationship to G. H. Darwin's primitive wrinkles. Then, besides the folding and plication of the crust in some areas, we have to account for the undoubted stretching which it has suffered in other places, stretching of a kind indicated by faults so common that they are generally known as normal faults. It has been estimated by Claypole that the folding of the Appalachian range resulted in a horizontal compression of the strata to a belt less than 65 per cent. of the original breadth. According to Heim the diameter of the northern zone of the central Alps is not more than half the original extension of the strata when they were laid down in horizontal sheets. De la Beche, in his memoir on Devon and Cornwall, which anticipated many problems of more than local interest, pointed out that, if the inclined and folded strata were flattened out again, they would cover far more ground than that to which they are now restricted on the geological map. Thus, according to Dutton, Fisher, and others, the mere contraction of the cooling globe is insufficient to account for our great rock-folds, especially great folds like those of the Alps and the Himalayas, which have been produced in quite late geological times. It is possible that this conclusion is in the main true; but in coming to this conclusion we must give due value to the number of patches which have been let into the old crustal envelope—masses of igneous rock, mineral veins and hydrated products which have been formed in areas of temporary stretching, and have remained as permanent additions to the crust, increasing the size and bagginess of the old coat, which, since the discovery of radium, is now regarded as much older than was formerly imagined by non-geological members of the scientific world.

The peculiar nature of rock-folds presents also an obstacle no less formidable from the qualitative point of view. If the skin were merely collapsing on its shrinking core we should expect wrinkles in all directions; yet we find great folded areas like the Himalayas stretching continuously for 1400 miles, with signs of a persistently directed overthrust from the north; or we have folded massss like the Appalachians of a similar order of magnitude stretching from Maine to Georgia, with an unmistakable compression in a north-west to south-east direction. The simple hypothesis of a collapsing crust is thus "quantitatively insufficient," according to Dutton, though this is still doubtful, and it is "qualitatively inapplicable," which is highly probable.

In addition to the facts that rock-folds are maintained over such great distances and that later folds are sometimes found to be superimposed on older ones, geologists have to account for the conditions which permit of the gradual accumulation of enormous thicknesses of strata without corresponding rise of the surface of deposition.

On the other hand, too, in folded regions there are exposures of beds superimposed on one another with a total thickness of many miles more than the height of any known mountain, and one is driven again to conclude that uplift has proceeded *pari passu* with the removal of the load through the erosive work of atmospheric agents.

It does not necessarily follow that these two processes are the direct result of loading in one case and

[19] Dutton, "On Some of the Greater Problems of Physical Geology," Bull. Phil. Soc. Wash., xi., 53, 1889.

of relief in the other; for slow subsidence gives rise to the conditions that favour deposition and the uplifting of a range results in the increased energy of eroding streams.

Thus there was a natural desire to see if Dutton's theory agreed with the variations of gravity. If the ups and downs are balanced, the apparently large mass of a mountain-range ought to be compensated by lightness of material in and below it. Dutton was aware of the fact that this was approximately true regarding the great continental plateaux and oceanic depressions; but he imagined that the balance was delicate enough to show up in a small hill-range of 3000 to 5000 feet.

The data required to test this theory, accumulated during the triangulation of the United States, have been made the subject of an elaborate analysis by J. F. Hayford and W. Bowie.[20] They find that, by adopting the hypothesis of isostatic compensation, the differences between the observed and computed deflections of the vertical caused by topographical inequalities are reduced to less than one-tenth of the mean values which they would have if no isostatic compensation existed. According to the hypothesis adopted, the inequalities of gravity are assumed to die out at some uniform depth, called the depth of compensation, below the mean sea-level. The columns of crust material standing above this horizon vary in length according to the topography, being relatively long in highlands and relatively short under the ocean. The shorter columns are supposed to be composed of denser material, so that the product of the length of each column by its mean density would be the same for all places. It was found that, by adopting 122 kilometres as the depth of compensation, the deflection anomalies were most effectually eliminated, but there still remained unexplained residuals or local anomalies of gravity to be accounted for.

Mr. G. K. Gilbert,[21] who was one of the earliest geologists to turn to account Dutton's theory of isostasy, has recently offered a plausible theory to account for these residual discrepancies between the observed deflections and those computed on the assumption of isostatic compensation to a depth of 122 kilometres. An attempt had already been made by Hayford and Bowie to correlate the distribution of anomalies with the main features of the geological map and with local changes in load that have occurred during comparatively recent geological times. For example, they considered the possibility of an increased load in the low Mississippi valley, where there has been in recent times a steady deposition of sediment, and therefore possibly the accumlation of mass slightly in advance of isostatic adjustment. One would expect in such a case that there would be locally shown a slight excess of gravity, but, on the contrary, there is a general prevalence of negative anomalies in this region. In the Appalachian region, on the other hand, where there has been during late geological times continuous erosion, with consequent unloading, one would expect that the gravity values would be lower, as isostatic compensation would naturally lag behind the loss of overburden; this, however, is also not the case, for over a greater part of the Appalachian region the anomalies are of the positive order. Similarly, in the north central region, where there has been since Pleistocene times a removal of a heavy ice-cap, there is still a general prevalence of positive anomalies.

These anomalies must, therefore, remain unexplained by any of the obvious phenomena at the command of the geologist. G. K. Gilbert now suggests that, while it may be true that the product of the length of the unit column by its mean density may be the same, the density variations within the column may be such as to give rise to different effects on the pendulum. If, for instance, one considers two columns of the same size and of exactly the same weight, with, in one case, the heavy material at a high level and in the other case with the heavy material a low level, the centre of gravity of the former column, being nearer the surface, will manifest itself with a greater pull on the pendulum; these columns would be, however, in isostatic adjustment.[22]

Gilbert's hypothesis thus differs slightly from the conception put forth by Hayford and Bowie; for Gilbert assumes that there is still appreciable heterogeneity in the more deep-seated parts of the earth, while Hayford and Bowie's hypothesis assumes that in the nuclear mass density anomalies have practically disappeared, and that there is below the depth of compensation an adjustment such as would exist in a mass composed of homogeneoûs concentric shells.

In order to make the Indian observations comparable with those of the United States as a test of the theory of isostasy, Major H. L. Crosthwait[23] has adopted Hayford's system of computation and has applied it to 102 latitude stations and 18 longitude stations in India. He finds that the unexplained residuals in India are far more pronounced than they are in the United States, or, in other words, it would appear that isostatic conditions are much more nearly realised in America than in India.

The number of observations considered in India is still too small for the formation of a detailed map of anomalies, but the country can be divided into broad areas which show that the mean anomalies are comparable with those of the United States only over the Indian peninsula, which, being a mass of rock practically undisturbed since early geological times, may be regarded safely as having approached isostatic equilibrium. To the north of the peninsula three districts form a wide band stretching west-north-westwards from Calcutta, with mean residual anomalies of a positive kind, while to the north of this band lies the Himalayan belt, in which there is always a large negative residual.

Colonel Burrard[24] has considered the Himalayan and sub-Himalayan anomalies in a special memoir, and comes to the conclusion that the gravity deficiency is altogether too great to be due to a simple geosynclinal depression filled with light alluvium such as we generally regard the Gangetic trough to be. He suggests that the rapid change in gravity values near the southern margin of the Himalayan mass can be explained only on the assumption of the existence of a deep and narrow rift in the sub-crust parallel to the general Himalayan axis of folding. A single

Bowie, "The Effect of Topography and Isostatic Compensation upon the Intensity of Gravity," "U.S. Coast and Geodetic Survey Special Publication No. 10," Washington, 1912.

[21] "Interpretation of Anomalies of Gravity," "U.S. Geol. Surv. Professional Paper," 85-C, 1913, p. 29.

[22] It is interesting to note that the idea suggested by G. K. Gilbert in 1913 was partly anticipated by Major H. L. Crosthwait in 1912 ("Survey of India, Professional Paper," No. 13, p. 5). Major Crosthwait, in discussing the similar gravity anomalies in India, remarks parenthetically: "Assuming the doctrine of isostasy to hold, is it not possible that in any two columns of matter extending from the surface down to the depth of compensation there may be the same mass, and yet that the density may be very differently distributed in the two columns? These two columns, though in isostatic equilibrium, would act differently on the plumb-line owing to the unequal distribution of mass.

"The drawback to treating this subject by hard and fast mathematical formulæ is that we are introducing into a discussion of the constitution of the earth's crust a uniform method when, in reality, probably no uniformity exists."

[23] "Survey of India, Professional Paper," No. 13, 1912.

[24] "Survey of India, Professional Paper," No. 12, 1912.

large rift of the kind and size that Colonel Burrard postulates is a feature for which we have no exact parallel; but one must be careful not to be misled by the use of a term which, while conveying a definite mental impression to a mathematician, appears to be incongruous with our geological experience. There may be no such thing as a single large rift filled with light alluvial material, but it is possible that there may still be a series of deep-seated fissures that might afterwards become filled with mineral matter.

With this conception of a rift or a series of rifts, Colonel Burrard is led to reverse the ordinary mechanical conception of Himalayan folding. Instead now of looking upon the folds as due to an overthrust from the north, he regards the corrugations to be the result of an under-creep of the sub-crust towards the north. Thus, according to this view, the Himalaya, instead of being pushed over like a gigantic rock-wave breaking on to the Indian *Horst*, is in reality being dragged away from the old peninsula, the depression between being filled up gradually by the Gangetic alluvium. So far as the purely stratigraphical features are concerned, the effect would be approximately the same whether there is a superficial overthrust of the covering strata or whether there is a deep-seated withdrawal of the basement which is well below the level of observation.

Since the Tibetan expedition of ten years ago we have been in possession of definite facts which show that to the north of the central crystalline axis of the Himalaya there lies a great basin of marine sediments forming a fairly complete record from Palæozoic to Tertiary times, representing the sediments which were laid down in the great central Eurasian ocean to which Suess gave the name *Tethys*. We have thus so far been regarding the central crystalline axis of the Himalaya as approximately coincident with the old northern coast-line of Gondwanaland; but, if Colonel Burrard's ideas be correct, the coast-line must have been very much further to the south before the Himalayan folding began.

Representing what the Geological Survey of India regards as the orthodox view, Mr. H. H. Hayden [25] has directed attention to some conclusions which, from our present geological knowledge, appear to be strange and improbable in Colonel Burrard's conclusions, and he also offers alternative explanations for the admitted geodetic facts. Mr. Hayden suggests, for instance, that the depth of isostatic compensation may be quite different under the Himalayan belt from that under the regions to the south. His assumptions, however, in this respect are, as pointed out by Colonel G. P. Lenox Conyngham,[26] at variance with the whole theory of isostasy. Mr. Hayden then suggests that most of the excessive anomalies would disappear if we took into account the low specific gravity of the sub-Himalayan sands and gravels of Upper Tertiary age as well as of the Pleistocene and recent accumulations of similar material filling the Indo-Gangetic depression. It would not be at all inconsistent with our ideas derived from geology to regard the Gangetic trough as some three or four miles deep near its northern margin, thinning out gradually towards the undisturbed mass of the Indian peninsula, and Mr. R. D. Oldham,[27] with this view, has also calculated the effect of such a wedge of alluvial material of low specific gravity, coming to the conclusion that the rapid change in deflection, on passing from the Lower Himalaya southward towards the peninsula, can mainly be explained by the deficiency of mass in the alluvium itself.

It is obvious that, before seeking for any unusual cause for the gravity anomalies, we ought to take into account the effect of this large body of alluvium which lies along the southern foot of the range. It is, however, by no means certain that a thick mass of alluvial material, accumulated slowly and saturated with water largely charged with carbonate of lime, would have a specific gravity so appreciably lower than that of the rocks now exposed in the main mass of the Himalaya as to account for the residual anomalies. Some of the apparent deficiency in gravity is due to this body of alluvium, but it will only be after critical examination of the data and more precise computation that we shall be in a position to say if there is still room to entertain Colonel Burrard's very interesting hypothesis.

By bringing together the geological and geodetic results we notice five roughly parallel bands stretching across northern India. There is (1) a band of abnormal high gravity lying about 150 miles from the foot of the mountains, detected by the plumb-line and pendulum; (2) the great depression filled by the Gangetic alluvium; (3) the continuous band of Tertiary rock, forming the sub-Himalaya, and separated by a great boundary overthrust from (4) the main mass of the Outer and Central Himalaya of old unfossiliferous rock, with the snow-covered crystalline peaks flanked on the north by (5) the Tibetan basin of highly fossiliferous rocks formed in the great Eurasian mediterranean ocean that persisted up to nearly the end of Mesozoic times.

That these leading features in North India can scarcely be without generic relationship one to another is indicated by the geological history of the area. Until nearly the end of the Mesozoic era the line of crystalline, snow-covered peaks now forming the Central Himalaya was not far from the shore-line between Gondwanaland, stretching away to the south, and Tethys, the great Eurasian ocean. Near the end of Mesozoic times there commenced the great outwelling of the Deccan Trap, the remains of which, after geological ages of erosion, still cover an area of 200,000 square miles, with a thickness in places of nearly 5000 ft. Immediately after the outflow of this body of basic lava, greater in mass than any known eruption of the kind, the ocean flowed into North-West India and projected an arm eastwards to a little beyond the point at which the Ganges now emerges from the hills. Then followed the folding movements that culminated in the present Himalayan range, the elevation developing first on the Bengal side, and extending rapidly to the north-west until the folds extended in a great arc for some 1400 miles from south-east to north-west.

New streams developed on the southern face of the now rising mass, and although the arm of the sea that existed in early Tertiary times became choked with silt, the process of subsidence continued, and the gradually subsiding depression at the foot of the hills as fast as it developed became filled with silt, sand, gravel, and boulders in increasing quantities as the hills became mountains and the range finally reached its present dimensions, surpassing in size all other features of the kind on the face of the globe.

Now, it is important to remember that for ages before the great outburst of Deccan Trap occurred there was a continual unloading of Gondwanaland, and a continual consequent overloading of the ocean beds immediately to the north; that this process went on with a gradual rise on one side and a gradual depression on the other; and that somewhere near and parallel to the boundary line the crust must have been undergoing stresses which resulted in strain, and, as I suggest, the development of those fissures that let loose the floods of Deccan Trap and brought to an end the delicate isostatic balance.

25 "Rec. Geol Surv. Ind.," vol. xliii., part 2, p. 138, 1913.
26 "Records of the Survey of India," vol. v., p. 1.
27 Proc. Roy. Soc., Series A, vol. xc., p. 32, 1914.

During the secular subsidence of the northern shore line of Gondwanaland, accompanied by the slow accumulation of sediment near the shore and the gradual filing away of the land above sea-level, there must have been a gradual creep of the crust in a northerly direction. Near the west end of the Himalayan arc this movement would be towards the north-west for a part of the time; at the east end the creep would be towards the north-north-east and north-east. Thus there would be a tendency from well back in Palæozoic times up to the end of the Cretaceous period for normal faults—faults of tension—to develop on the land, with a trend varying from W.S.W.–E.N.E. to W.N.W.–E.S.E. across the northern part of Gondwanaland. We know nothing of the evidence now pigeon-holed below the great mantle of Gangetic alluvium, while the records of the Himalayan region have been masked or destroyed by later foldings. But in the stratified rocks lying just south of the southern margin of the great alluvial belt we find a common tendency for faults to strike in this way across the present Peninsula of India. These faults have, for instance, marked out the great belt of coalfields stretching for some 200 miles from east to west in the Damuda valley. On this, the east side of India, the fractures of tension have a general trend of W.N.W.–E.S.E. We know that these faults are later than the Permian period, but some of them certainly were not much later.

If now we go westwards across the Central Provinces and Central India into the eastern part of the Bombay Presidency, we find records of this kind still more strikingly preserved; for where the Gondwana rocks, ranging from Permo-Carboniferous to Liassic in age, rest on the much older Vindhyan series, we find three main series of these faults. One series was developed before Permo-Carboniferous times; another traverses the lower Gondwanas, which range up to about the end of Permian times; while the third set affects the younger and Upper Gondwanas of about Rhætic or Liassic age. Although the present topography of the country follows closely the outlines of the geological formations, it is clear from the work of the Geological Survey of India that these outlines were determined in Mesozoic times, and that the movements which formed the latest series of faults were but continuations of those which manifested themselves in Palæozoic times. According to Mr. J. G. Medlicott, the field data showed "that a tendency to yield in general east and west or more clearly north-east and south-west lines existed in this great area from the remote period of the Vindhyan fault." [28] The author of the memoir and map on this area was certainly not suspicious of the ideas of which I am now unburdening my mind; on the contrary, he attempted, and, with apologies, failed to reconcile his facts to views then being pushed by the weight of "authority" in Europe. This was not the last time that facts established in India were found (to use a field-geologist's term) unconformably to lie on a basement of geological orthodoxy as determined by authority in Europe. It is important to notice that the series of faults referred to in the central parts of India are not mere local dislocations, but have a general trend for more than 250 miles.

A fault must be younger, naturally, than the strata which it traverses, but how much younger can seldom be determined. Intrusive rocks of known age are thus often more useful in indicating the age of the fissures through which they have been injected, and consequently the dykes which were formed at the time of the eruption of the great Deccan Trap give another clue to the direction of stresses at this critical time, that is, towards the end of the Cretaceous period, when the northerly creep had reached its maximum, just before Gondwanaland was broken up. If, now, we turn to the geological maps of the northern part of Central India, the Central Provinces, and Bengal, we find that the old Vindhyan rocks of the Narbada valley were injected with hundreds of trap-dykes which show a general W.S.W.–E.N.E. trend, and thus parallel to the normal tension faults, which we know were formed during the periods preceding the outburst of the Deccan Trap. This general trend of faults and basic dykes is indicated on many of the published geological maps of India covering the northern part of the peninsula, including Ball's maps of the Ramgarh and Bokaro coalfields [29] and of the Hutar coalfield,[30] Hughes's Rewa Gondwana basin, [31] Jones's southern coalfields of the Satpura basin,[32] and Oldham's general map of the Son valley.[33]

We see, then, that the development of fissures with a general east-west trend in the northern part of Gondwanaland culminated at the end of the Cretaceous period, when they extended down, probably, to the basic magma lying below the crust either in a molten state, or in a state that would result in fluxion on the relief of pressure. That the molten material came to the surface in a superheated and liquid condition is shown by the way in which it has spread out in horizontal sheets over such enormous areas. Throughout this great expanse of lava there are no certain signs of volcanic centres no conical slopes around volcanic necks; and one might travel for more than 400 miles from Poona to Nagpur over sheets of lava which are still practically horizontal. There is nothing exactly like this to be seen elsewhere to-day. The nearest approach to it is among the Hawaiian calderas, where the highly mobile basic lavas also show the characters of superfusion, glowing, according to J. D. Dana,[34] with a white heat, that is, at a temperature not less than about 1300° C.

Mellard Reade has pointed out that the earth's crust is under conditions of stress analogous to those of a bent beam, with, at a certain depth, a "level of no strain." Above this level there should be a shell of compression, and under it a thicker shell of tension. The idea has been treated mathematically by C. Davison, G. H. Darwin, O. Fisher, and M. P. Rudski, and need not be discussed at present. Prof. R. A. Daly has taken advantage of this view concerning the distribution of stresses in the crust to explain the facility for the injection of dykes and batholiths from the liquid, or potentially liquid, gabbroid magma below into the shell of tension.[35] He also shows that the injection of large bodies of basic material into the shell of tension tends on purely mechanical grounds to the formation of a depression, or geosyncline. If this be so, are we justified in assuming that the heavy band following the southern margin of the Gangetic geosyncline is a "range" of such batholiths? The idea is not entirely new; for O. Fisher made the suggestion more than twenty years ago that the abnormal gravity at Kalianpur was due to "some peculiar influence (perhaps of a volcanic neck of basalt)." [36]

Daly's suggestion, however, taken into account with the history of Gondwanaland, may explain the peculiar alignment of the heavy subterranean band, parallel to the Gangetic depression and parallel to the general trend of the peninsular tension-faults and fissures that

followed the unloading of Gondwanaland and the heavy loading of the adjoining ocean bed along a band roughly parallel to the present Himalayan folds.

R. S. Woodward objected that isostasy does not seem to meet the requirements of geological continuity, for it tends rapidly towards stable equilibrium, and the crust ought therefore to reach a stage of repose early in geologic time.[37] If the process of denudation and rise, with adjoining deposition and subsidence, occurred on a solid globe, this objection might hold good. But it seems to me that the break-up of Gondwanaland and the tectonic revolutions that followed show how isostasy can defeat itself in the presence of a subcrustal magma actually molten or ready to liquefy on local relief of pressure. It is possible that the protracted filing off of Gondwanaland brought nearer the surface what was once the local level of no-strain and its accompanying shell of tension.

The conditions existing in northern Gondwanaland before late Mesozoic times must have been similar to those in south-west Scotland before the occurrence of the Tertiary eruptions, for the crust in this region was also torn by stresses in the S.W.–N.E. direction with the formation of a remarkable series of N.W.–S.E. dykes which give the 1-in. geological maps in this region a regularly striped appearance.

There is no section of the earth's surface which one can point to as being now subjected to exactly the same kind and magnitude of treatment as that to which Gondwanaland was exposed for long ages before the outburst of the Deccan Trap; but possibly the erosion of the Brazilian highlands and the deposition of the silt carried down by the Amazon, with its southern tributaries, and by the more eastern Araguay and Tocantins, may result in similar stresses which, if continued, will develop strains, and open the way for the subjacent magma to approach the surface or even to become extravasated, adding another to the small family of so-called fissure-eruptions.

The value of a generalisation can be tested best by its trustworthiness as a basis for prediction. Nothing shows up the shortcomings of our knowledge about the state of affairs below the superficial crust so effectually as our inability to make any useful predictions about earthquakes or volcanic eruptions. For many years to come in this department of science the only worker who will ever establish a claim to be called a prophet will be one in Cicero's sense—"he who guesses well."

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY PROF. ARTHUR DENDY, D.Sc., F.R.S., PRESIDENT OF THE SECTION.

Progressive Evolution and the Origin of Species.

THE opening years of the present century have witnessed a remarkable development of biology as an experimental science, a development which, however full of promise it may be for the future, for the time being appears to have resulted in a widespread disturbance of ideas which have themselves only recently succeeded in gaining general acceptance. The theory of organic evolution, plainly enough enunciated at the close of the eighteenth and the beginning of the nineteenth century by Buffon, Lamarck, and Erasmus Darwin, remained unconvincing to the great majority of thinking men until the genius of Charles Darwin not only brought together and presented the evidence in such a manner that it could no longer be ignored, but elaborated a logical explanation of the way in which organic evolution might be supposed to have taken place. Thanks to his labours and those of Alfred Russel Wallace, supported by the powerful influence of such men as Huxley and Hooker, the theory was placed upon a firm foundation, in a position which can never again be assailed with any prospect of success.

This statement is, I believe, entirely justified with regard to the theory of organic evolution itself, but the case is very different when we come to investigate the position of the various subsidiary theories which have been put forward from time to time with regard to what may perhaps be termed the *modus operandi*, the means by which organic evolution has been effected. It is in this field that controversy rages more keenly than ever before. Lamarck told us that evolution was due to the accumulated results of individual effort in response to a changing environment, and also to the direct action of the environment upon the organism. Darwin and Wallace taught us that species originated by the natural selection of favourable variations, and under the influence of Weismann's doctrine of the non-inheritance of acquired characters the theory of natural selection is in danger of becoming crystallised into an inflexible dogma. In recent years De Vries has told us that species arise by sudden mutations, and not by slow successive changes, while one of the most extreme exponents of "Mendelism," Prof. Lotsy, lately informed us that all species arise by crossing, and seriously suggested that the vertebrate type arose by the crossing of two invertebrates!

This curious and many-sided divergence of opinion amongst expert biologists is undoubtedly largely due to the introduction of experimental methods into biological science. Such methods have proved very fruitful in results which at first sight seem to be mutually contradictory, and each group of workers has built up its own theory mainly on the basis of observations in its own restricted field.

Prof. Bateson has said in his recently published "Problems of Genetics": "When . . . we contemplate the problem of evolution at large the hope at the present time of constructing even a mental picture of that process grows weak almost to the point of vanishing. We are left wondering that so lately men in general, whether scientific or lay, were so easily satisfied. Our satisfaction, as we now see, was chiefly founded on ignorance."[1]

In view of this striking pronouncement on the part of one who has devoted his life with signal success to the experimental investigation of evolutionary problems, the remarks which I propose to lay before you for your consideration to-day may well appear rash and ill-advised. I cannot believe, however, that the position is really quite so black as it is painted. We must perforce admit that the divers theories with regard to the working of organic evolution cannot all be correct in all their details, but it may be that each contains its own elements of truth, and that if these elements can but be recognised and sorted out, they may perhaps be recombined in such a form as to afford at any rate a plausible working hypothesis. We must bear in mind from the outset that in dealing with such a complex problem many factors have to be taken into account, and that widely different views on the question may be merely one-sided and not necessarily mutually exclusive.

I take it there are three principal facts, or groups of facts, that have to be accounted for by any theory of organic evolution:—

(1) The fact that, on the whole, evolution has taken

[37] "Address to the Sect. of Mathematics and Astronomy of the Amer. Assoc.," 1889. Smithsonian Report, 1890. p. 196.

[1] "Problems of Genetics," p. 97.

place in a progressive manner along definite and divergent lines.

(2) The fact that individual animals and plants are more or less precisely adapted in their organisation and in their behaviour to the conditions under which they have to live.

(3) The fact that evolution has resulted in the existence on the earth to-day of a vast number of more or less well-defined groups of animals and plants which we call species.

The first of these facts appears to me to be the most fundamental, and at the same time the one to which least attention is usually paid. The great question, after all, is, Why do organisms progress at all instead of remaining stationary from generation to generation? To answer this question it is not necessary to go back to the beginning and consider the case of the first terrestrial organisms, whatever they may have been, nor are we obliged to take as illustrations the lowest organisms known to us as existing at the present day. We may consider the problem at any stage of evolution, for at each stage progress is, or may be, still taking place. We may even begin by considering what is usually regarded as the highest stage of all, man himself; and indeed this seems the most natural thing to do, for we certainly know more about the conditions of progress in man than in any other organism. I refer, of course, at the moment, not to progress in bodily organisation, but to progress in the ordinary sense of the word, the progress, say, of a family which rises in the course of a few generations from a position of obscure poverty to one of wealth and influence. You may perhaps say that such a case has no bearing upon the problem of organic evolution in a state of nature, and that we ought to confine our attention to the evolution of bodily structure and function. If so, I must reply that you have no right to limit the meaning of the term evolution in this manner; the contrast between man and nature is purely arbitrary; man is himself a living organism, and all the improvements that he effects in his own condition are part of the progress of evolution in his particular case. At any rate I must ask you to accept this case as our first illustration of a principle that may be applied to organisms in general.

If we inquire into the cause of the progress of our human family I think there can be only one answer—it is due to the accumulation of capital, or, as I should prefer to put it, to the accumulation of potential energy, either in the form of material wealth or of education. What one generation saves is available for the next, and thus each succeeding generation gets a better start in life, and is able to rise a little higher than the preceding one.

Every biologist knows, of course, that there are many analogous cases amongst the lower animals, and also amongst plants. The accumulation of food-yolk in the egg has undoubtedly been one of the chief factors in the progressive evolution of animals, although it has been replaced in the highest forms by a more effective method of supplying potential energy to the developing offspring. It may indeed be laid down as a general law that each generation, whether of animals or of plants, accumulates more energy than it requires for its own maintenance, and uses the surplus to give the next generation a start in life. There is every reason to believe that this has been a progressive process throughout the whole course of evolution, for the higher the degree or organisation the more perfect do we find the arrangements for securing the welfare of the offspring.

We cannot, of course, trace this process back to its commencement, because we know nothing of the nature of the earliest living things, but we may pause for a moment to inquire whether any phenomena occur amongst simple unicellular organisms that throw any light upon the subject. What we want to know is—How did the habit of accumulating surplus energy and handing it on to the next generation first arise?

Students of Prof. H. S. Jennings's admirable work on the "Behaviour of the Lower Organisms" will remember that his experiments have led him to the conclusion that certain Protozoa, such as Stentor, are able to learn by experience how to make prompt and effective responses to certain stimuli; that after they have been stimulated in the same way a number of times they make the appropriate response at once without having to go through the whole process of trial and error by which it was first attained. In other words, they are able by practice to perform a given action with less expenditure of energy. Some modification of the protoplasm must take place which renders the performance of an act the easier the oftener it has been repeated. The same is, of course, true in the case of the higher animals, and we express the fact most simply by saying that the animal establishes habits. From the mechanistic point of view we might say that the use of the machine renders it more perfect and better adapted for its purpose. In the present state of our knowledge I think we cannot go beyond this, but must content ourselves with recognising the power of profiting by experience as a fundamental property of living protoplasm.

It appears to me that this power of profiting by experience lies at the root of our problem, and that in it we find a chief cause of progressive evolution. Jennings speaks of the principle involved here as the "Law of the readier resolution of physiological states after repetition," and, similarly, I think we must recognise a "Law of the accumulation of surplus energy" as resulting therefrom. Let us look at the case of the accumulation of food-yolk by the egg-cell a little more closely from this point of view. Every cell takes in a certain amount of potential energy in the form of food for its own use. If it leads an active life, either as an independent organism or as a constituent part of an organism, it may expend by far the greater part, possibly even the whole, of that energy upon its own requirements, but usually something is left over to be handed down to its immediate descendants. If, on the other hand, the cells exhibits very little activity and expends very little energy, while placed in an environment in which food is abundant, it will tend to accumulate surplus energy in excess of its own needs. Such is the case with the egg-cells of the multicellular animals and plants. Moreover, the oftener the process of absorbing food-material is repeated the easier does it become; in fact, the egg-cell establishes a habit of storing up reserve material or food-yolk. Inasmuch as it is a blastogenic character, there can be no objection to the supposition that this habit will be inherited by future generations of egg-cells. Indeed we are obliged to assume that this will be the case, for we know that the protoplasm of each succeeding generation of egg-cells is directly continuous with that of the preceding generation. We thus get at any rate a possibility of the progressive accumulation of potential energy in the germ-cells of successive generations of multicellular organisms, and, of course, the same argument holds good with regard to successive generations of Protista.

It would seem that progressive evolution must follow as a necessary result of the law of the accumulation of surplus energy in all cases where there is nothing to counteract that law, for each generation gets a better start than its predecessor, and is able to carry on a little further its struggle for existence with the environment. It may be said that this argument

proves too much, that if it were correct all organisms would by this time have attained to a high degree of organisation, and that at any rate we should not expect to find such simple organisms as bacteria and Amœbæ still surviving. This objection, which, of course, applies equally to other theories of organic evolution, falls to the ground when we consider that there must be many factors of which we know nothing which may prevent the establishment of progressive habits and render impossible the accumulation of surplus energy. Many of the lower organisms, like many human beings, appear to have an inherent incapacity for progress, though it may be quite impossible for us to say to what that incapacity is due.

It will be observed that in the foregoing remarks I have concentrated attention upon the storing up of reserve material by the egg-cells, and in so doing have avoided the troublesome question of the inheritance of so-called acquired characters. I do not wish it to be supposed, however, that I regard this as the only direction in which the law of the accumulation of surplus energy can manifest itself, for I believe that the accumulation of surplus energy by the body may be quite as important as a factor in progressive evolution as the corresponding process in the germ-cells themselves. The parents, in the case of the higher animals, may supply surplus energy, in the form of nutriment or otherwise, to the offspring at all stages of its development, and the more capital the young animal receives the better will be its chances in life, and the better those of its own offspring.

In all these processes, no doubt, natural selection plays an important part, but, in dealing with the accumulation of food material by the egg-cells, one of my objects has been to show that progressive evolution would take place even if there were no such thing as natural selection, that the slow successive variations in this case are not chance variations, but due to a fundamental property of living protoplasm and necessarily cumulative.

Moreover, the accumulation of surplus energy in the form of food-yolk is only one of many habits which the protoplasm of the germ-cells may acquire in a cumulative manner. It may learn by practice to respond with increased promptitude and precision to other stimuli besides that of the presence of nutrient material in its environment. It may learn to secrete a protective membrane, to respond in a particular manner to the presence of a germ-cell of the opposite sex, and to divide in a particular manner after fertilisation has taken place.

Having thus endeavoured to account for the fact that progressive evolution actually occurs by attributing it primarily to the power possessed by living protoplasm of learning by experience and thus establishing habits by which it is able to respond more quickly to environmental stimuli, we have next to inquire what it is that determines the definite lines along which progress manifests itself.

Let us select one of these lines and investigate it as fully as the time at our disposal will permit, with the view of seeing whether it is possible to formulate a reasonable hypothesis as to how evolution may have taken place. Let us take the line which we believe has led up to the evolution of air-breathing vertebrates. The only direct evidence at our disposal in such a case is, of course, the evidence of palæontology, but I am going to ask you to allow me to set this evidence, which, as you know, is of an extremely fragmentary character, aside, and base my remarks upon the ontogenetic evidence, which, although indirect, will, I think, be found sufficient for our purpose. One reason for concentrating our attention upon this aspect of the problem is that I wish to show that the recapitulation of phylogenetic history in individual development is a logical necessity if evolution has really taken place.

We may legitimately take the nucleated Protozoon cell as our starting point, for, whatever may have been the course of evolution that led up to the cell, there can be no question that all the higher organisms actually start life in this condition.

We suppose, then, that our ancestral Protozoon acquired the habit of taking in food material in excess of its own requirements, and of dividing into two parts whenever it reached a certain maximum size. Here again we must, for the sake of simplicity, ignore the facts that even a Protozoon is by no means a simple organism, and that its division, usually at any rate, is a very complicated process. Each of the daughter-cells presently separates from its sister-cell and goes its own way as a complete individual, still a Protozoon. It seems not improbable that the separation may be due to the renewed stimulus of hunger, impelling each cell to wander actively in search of food. In some cases, however, the daughter-cells remain together and form a colony, and probably this habit has been rendered possible by a sufficient accumulation of surplus energy in the form of food-yolk on the part of the parent rendering it unnecessary for the daughter-cells to separate in search of food at such an early date. One of the forms of colony met with amongst existing Protozoa is the hollow sphere, as we see it, for example, in Sphærozoum and Volvox, and it is highly probable that the assumption of this form is due largely, if not entirely, to what are commonly called mathematical causes, though we are not in a position to say exactly what these causes may be. The widespread occurrence of the blastosphere or blastula stage in ontogeny is a sufficiently clear indication that the hollow, spherical Protozoon colony formed a stage in the evolution of the higher animals.

By the time our ancestral organism has reached this stage, and possibly even before, a new complication has arisen. The cells of which the colony is composed no longer remain all alike, but become differentiated, primarily into two groups, which we distinguish as somatic-cells and germ-cells respectively.

From this point onwards evolution ceases to be a really continuous process, but is broken up into a series of ontogenies, at the close of each of which the organism has to go back and make a fresh start in the unicellular condition, for the somatic cells sooner or later become exhausted in their conflict with the environment and perish, leaving the germ-cells behind to take up the running. That the germ-cells do not share the fate of the somatic cells must be attributed to the fact that they take no part in the struggle for existence to which the body is exposed. They simply multiply and absorb nutriment under the protection of the body, and therefore retain their potential energy unimpaired. They are in actual fact, as is so often said, equivalent to so many protozoa, and, like the protozoa, are endowed with a potential immortality.

We know that, if placed under suitable conditions, or in other words, if exposed to the proper environmental stimuli, these germ-cells will give rise to new organisms, like that in the body of which they were formerly enclosed. One of the necessary conditions is, with rare exceptions, the union of the germ-cells in pairs to form zygotes or fertilised ova; but I propose, in the first instance, for the sake of simplicity, to leave out of account the existence of the sexual process and the results that follow therefrom, postponing the consideration of these to a later stage of our inquiry. I wish, moreover, to make it quite clear that organic evolution must have taken place if no such event as amphimixis had ever occurred.

What, then, may the germ-cells be expected to do?

How are they going to begin their development? In endeavouring to answer this question we must remember that the behaviour of an organism at any moment depends upon two sets of factors—the nature of its own constitution on one hand, and the nature of its environment on the other. If these factors are identical for any two individual organisms, then the behaviour of these two individuals must be the same. If the germ-cells of any generation are identical with those of the preceding generation, and if they develop under identical conditions, then the soma of the one generation must also be identical with that of the other.[2] Inasmuch as they are parts of the same continuous germ-plasm—leaving out of account the complications introduced by amphimixis—we may assume that the germ-cells of the two generations are indeed identical in nearly every respect; but there will be a slight difference, due to the fact that those of the later generation will have inherited a rather larger supply of initial energy and a slightly greater facility for responding to stimuli of various kinds, for the gradual accumulation of these properties will have gone a stage further. The environment also will be very nearly identical in the two cases, for we know from experiment that if it were not the organism could not develop at all.

Throughout the whole course of its ontogeny the organism must repeat with approximate accuracy the stages passed through by its ancestors, because at every stage there will be an almost identical organism exposed to almost identical stimuli. We may, however, expect an acceleration of development and a slight additional progress at the end of ontogeny as the result of the operation of the law of the accumulation of surplus energy and of the slightly increased facility in responding to stimuli. The additional progress, of course, will probably be so slight that from one generation to the next we should be quite unable to detect it, and doubtless there will be frequent backslidings due to various causes.

We can thus formulate a perfectly reasonable explanation of how it is that the egg first undergoes segmentation and then gives rise to a blastula resembling a hollow protozoon colony; it does so simply because at every stage it must do what its ancestors did under like conditions. We can also see that progressive evolution must follow from the gradual accumulation of additions at the end of each ontogeny, these additions being rendered possible by the better start which each individual gets at the commencement of its career.

Let us now glance for a moment at the next stage in phylogeny, the conversion of the hollow spherical protozoon colony into the cœlenterate type of organisation, represented in ontogeny by the process of gastrulation. Here again it is probable that this process is explicable to a large extent upon mechanical principles. According to Rhumbler,[3] the migration of endoderm cells into the interior of the blastula is partly due to chemotaxis and partly to changes of surface tension, which decreases on the inner side of the vegetative cells owing to chemical changes set up in the blastocœl fluid.

We may, at this point, profitably ask the question, Is the endoderm thus formed an inherited feature of the organism? The material of which it is composed is, of course, derived from the egg-cell continuously by repeated cell-division, but the way in which that material is used by the organism depends upon the environment, and we know from experiment that modifications of the environment actually do produce corresponding modifications in the arrangement of the material. We know, for example, that the addition of salts of lithium to the water in which certain embryos are developing causes the endoderm to be protruded instead of invaginated, so that we get a kind of inside-out gastrula, the well-known lithium larva.

It appears, then that an organism really inherits from its parents two things: (1) a certain amount of protoplasm loaded with potential energy, with which to begin operations, and (2) an appropriate environment. Obviously the one is useless without the other. An egg cannot develop unless it is provided with the proper environment at every stage. Therefore, when we say that an organism inherits a particular character from its parents, all we mean is that it inherits the power to produce that character under the influence of certain environmental stimuli.[4] The inheritance of the environment is of at least as much importance as the inheritance of the material of which the organism is composed. The latter, indeed, is only inherited to a very small extent, for the amount of material in the egg-cell may be almost infinitesimal in comparison with the amount present in the adult, nearly the whole of which is captured from the environment and assimilated during ontogeny.

From this point of view the distinction between somatogenic and blastogenic characters really disappears, for all the characters of the adult organism are acquired afresh in each generation as a result of response to environmental stimuli during development. This is clearly indicated by the fact that you cannot change the stimuli without changing the result.

Time forbids us to discuss the phylogenetic stages through which the cœlenterate passed into the cœlomate type, the cœlomate into the chordate, and the chordate into the primitive vertebrate. We must admit that as yet we know nothing of the particular causes that determined the actual course of evolution at each successive stage. What we do know, however, about the influence of the environment, both upon the developing embryo and upon the adult, is sufficient to justify us in believing that every successive modification must have been due to a response on the part of the organism to some environmental change. Even if the external conditions remained practically identical throughout long periods of time, we must remember that the internal conditions would be different in each generation, because each generation starts with a slightly increased capital and carries on its development a little further under internal conditions modified accordingly.

At this point it may be asked, Is the response to environmental stimuli a purely mechanical one, and, if so, how can we account for the fact that at every stage in its evolution the organism is adapted to its environment? We shall have to return to this question later on, but it may be useful to point out once more that there is good reason to believe—especially from the experimental work of Jennings—that the response of even a unicellular organism to stimuli is to a large extent purposive; that the organism learns by experience, by a kind of process of trial and error, how to make the response most favourable to itself under any given change of conditions; in other words, that the organism selects those modes of response that are most conducive to its own well-being. Under the term response to stimuli we must, of course, include those responses of the living protoplasm which result in modifications of bodily structure, and hence the evolution of bodily structure will, on the whole, be

[2] This is, of course, a familiar idea. Compare Driesch, "Gifford Lectures," 1907, p. 214.

[3] Quoted by Przibram, "Experimental Zoology," English Trans., Part i., p. 47.

[4] Compare Dr. Archdall Reid's suggestive essay on "Biological Terms" (*Bedrock*, January, 1914).

of an adaptive character and will follow definite lines There is good reason for believing, however, that many minor modifications in structure may arise and persist, incidentally as it were, that have no significance as adaptations.

One of the most remarkable and distinctive features of the lower vertebrates is the presence of gill-slits as accessory organs of respiration. These gill-slits are clearly an adaptation to aquatic life. When the ancestors of the higher vertebrates left the water and took to life on land the gills disappeared and were replaced by lungs, adapted for air-breathing. The change must, of course, have been an extremely gradual one, and we get a very clear indication of how it took place in the surviving dipnoids, which have remained in this respect in an intermediate condition between the fishes and the amphibia, possessing and using both gills and lungs.

We also know that even the most highly specialised air-breathing vertebrates, which never live in water and never require gills or gill-slits at all, nevertheless possess very distinct gill-slits during a certain period of their development. This is one of the most familiar illustrations of the law of recapitulation, and my only excuse for bringing it forward now is that I wish, before going further, to consider a difficulty—perhaps more apparent than real—that arises in connection with such cases.

It might be argued that if gill-slits arose in response to the stimuli of aquatic life, and if these stimuli are no longer operative in the case of air-breathing vertebrates, then gill-slits ought not to be developed at any stage of their existence. This argument is, I think, fully met by the following considerations.

At any given moment of ontogenetic development the condition of any organ is merely the last term of a series of morphogenetic stages, while its environment at the same moment—which, of course, includes its relation to all the other organs of the body—is likewise merely the last term of a series of environmental stages. We have thus two parallel series of events to take into consideration in endeavouring to account for the condition of any part of an organism —or of the organism as a whole—at any period of its existence:—

E_1 E_2 E_3 ... ... E_n environmental stages
M_1 M_2 M_3 ... ... M_n morphogenetic ,,

Ontogeny is absolutely conditioned by the proper correlation of the stages of these two series at every point, and hence it is that any sudden change of environment is usually attended by disastrous consequences. Thus, after the fish-like ancestors of air-breathing vertebrates had left the water and become amphibians, they doubtless still had to go back to the water to lay their eggs, in order that the eggs might have the proper conditions for their development.

Obviously the environment can only be altered with extreme slowness, and one of the first duties of the parent is to provide for the developing offspring conditions as nearly as possible identical with those under which its own development took place. It is, however, inevitable that, as phylogenetic evolution progresses, the conditions under which the young organism develops should change. In the first place, the mere tendency to acceleration of development, to which we have already referred, must tend to dislocate the correlation between the ontogenetic series and the environmental series. Something of this kind seems to have taken place in the life-cycle of many hydrozoa, resulting in the suppression of the free medusoid generation and the gradual degeneration of the gonophore. But it is probably in most cases change in the environment of the adult that is responsible for such dislocation.

To return to the case of the amphibians. At the present day some amphibians, such as the newts and frogs, still lay their eggs in water, while the closely related salamanders retain them in the oviducts until they have developed into highly organised aquatic larvæ, or even what is practically the adult condition. Kammerer has shown that the period at which the young are born can be varied by changing the environment of the parent. In the absence of water the normally aquatic larvæ of the spotted salamander may be retained in the oviduct until they have lost their gills, and they are then born in the fully-developed condition, while, conversely, the alpine salamander, of which the young are normally born in the fully-developed state, without gills, may be made to deposit them prematurely in water in the larval, gill-bearing condition.

There can be no doubt that the ancestral amphibians laid their eggs in water in a completely undeveloped condition. The habit of retaining them in the body during their development must have arisen very gradually in the phylogenetic history of the salamanders, the period for which the young were retained growing gradually longer and longer. It is obvious that this change of habit involves a corresponding change in the environmental conditions under which the young develop, and in cases in which the young are not born until they have reached practically the adult condition this change directly affects practically the whole ontogeny. We may say that the series

E_1 E_2 E_3 ... ... E_n has become
E_1' E_2' E_3' ... ... E_n'

and as the change of environment must produce its effect upon the developing organism the series

M_1 M_2 M_3 ... ... M_n will have become
M_1' M_2' M_3' ... ... M_n'

We must remember that throughout the whole course of phylogenetic evolution this series is constantly lengthening, so that what was the adult condition at one time becomes an embryonic stage in future generations, and the series thus represents not only the ontogeny, but also, though in a more or less imperfect manner, the phylogeny of the organism.

The character of each stage in ontogeny must depend upon (1) the morphological and physiological constitution of the preceding stage, and (2) the nature of the environment in which development is taking place. We cannot, however, distinguish sharply between those two sets of factors, for, in a certain sense, the environment gradually becomes incorporated in the organism itself as development proceeds, each part contributing to the environment of all the remainder, and the influence of this internal portion of the environment ever becoming more and more important.

The whole process of evolution depends upon changes of environment taking place so gradually that the necessary self-adjustment of the organism at every stage is possible. In the case of our amphibia the eggs could possibly undergo the first stages of development, the preliminary segmentation, within the oviduct of the parent just as well as in the water, for in both cases they would be enclosed in their envelopes, and the morphological differences between the early stages in the two cases might be expected to be quite insignificant. But it must be the same at each term of the series, for each term is built upon the foundation of the preceding one, and the whole process takes place by slow and imperceptible degrees.

It is true that by the time we reach the formation of the vestigial gill-slits in the embyro of one of the higher vertebrates the environmental conditions are very different from those under which gill-slits were developed in their aquatic ancestors. But what then?

Are not the gill-slits also very different? The changed environment has had its effect. The gills themselves are never developed, and the gill-slits never become functional; moreover, they disappear completely at later stages of development, when the conditions of life become still more different and their presence would be actually detrimental to their possessor. The embyro with the vestigial gill-slits is, as a whole, perfectly well adapted to its environment, though the gill-slits themselves have ceased to be adaptive characters. They still appear because the environmental conditions, and especially the internal conditions, which have now become far more important than the external ones, are still such as to cause them to do so.

I think the chief difficulty in forming a mental picture of the manner in which evolution has taken place, and especially in accounting for the phenomenon of recapitulation in ontogeny, which is merely another aspect of the same problem, arises from attempting to take in too much at once. There is no difficulty in understanding how any particular stage is related to the corresponding stage in the previous generation, and the whole series of stages, whether looked at from the ontogenetic or from the phylogenetic point of view, can be nothing else but the sum of its successive terms.

It will be convenient, before going further, to sum up the results at which we have so far arrived from the point of view of the theory of heredity. We have as yet seen no reason to distinguish between somatogenic and blastogenic characters. All the characters of the adult animal are acquired during ontogeny as the result of the reaction of the organism to environmental stimuli, both internal and external. All that the organism actually inherits is a certain amount of protoplasm—endowed with a certain amount of energy—and a certain sequence of environmental conditions. In so far as these are identical in any two successive generations the final result must be identical also, the child must resemble the parent; in so far as they are different the child will differ from the parent, but the differences in environment cannot be very great without preventing development altogether.

So far, it is clear, there has been no need to think of the germ-cells as the bearers of material factors or determinants that are responsible for the appearance of particular characters in the adult organism; nor yet to suppose that they are, to use the phraseology of the mnemic theory of heredity, charged with the memories of past generations. They have been regarded as simple protoplasmic units, and the entire ontogeny has appeared as the necessary result of the reaction between the organism and its environment at each successive stage of development. This cannot, however, be a complete explanation of ontogeny, for if it were we should expect all eggs, when allowed to develop under the same conditions from start to finish, to give rise to the same adult form, and this we know is not the case. We know also, from observation and experiment, that the egg is in reality by no means a simple thing but an extremely complex one, and that different parts of the egg may be definitely correlated with corresponding parts of the adult body. It has been demonstrated in certain cases that the egg contains special organ-forming substances definitely located in the cytoplasm, and that if these are removed definite parts of the organism into which the egg develops will be missing. We know, also, that the nucleus of the germ-cell of either sex contains—at any rate, at certain periods—a number of perfectly well-defined bodies, the chromosomes, and these also have been definitely correlated in certain cases with special features of the adult organisation.

Before we can hope to complete our mental picture of the manner in which organic evolution has taken place, if only in outline, it is evident that we must be able to account for the great complexity of structure which the germ-cells themselves have managed to acquire, and also to form some idea of the effect of this complication upon the development of both the individual and the race.

We must consider the origin of cytoplasmic and nuclear complications of the egg separately, for they appear to be due fundamentally to two totally distinct sets of factors. In the first place we have to remember that during oogenesis the egg-cell grows to a relatively large size by absorbing nutrient material from the body in which it is enclosed. It is this nutrient material that is used for building up the deutoplasm or food-yolk. There is good reason for believing that the character of this nutrient material will change, during the course of evolution, *pari passu* with the changing character of the organism by which it is supplied. Doubtless the change is of a chemical nature, for we know from precipitin experiments that the body fluids of closely allied species, or even of the two sexes of the same species, do exhibit distinctly recognisable differences in chemical composition. It also appears highly probable, if not certain, from such experiments as those of Agar upon Simocephalus, that substances taken in with the food, which bring about conspicuous modifications of bodily structure, may at the same time be absorbed and stored up by the egg-cells so as to bring about corresponding changes in the adults into which the eggs develop.

There seems therefore to be no great difficulty in comprehending, at any rate in a general way, how the egg may become the repository of definite chemical substances, organ-forming substances if we like to call them so, possibly to be classed with the hormones and enzymes, which will influence the development in a particular manner as soon as the appropriate conditions arise.

Unfortunately, time will not allow of our following up this line of thought on the present occasion, but we may notice, before passing on, that with the accumulation of organ-forming substances in the egg we have introduced the possibility of changes in bodily structure, to whatever cause they may be due, being represented by correlated modifications in the germ-cells, and this is doubtless one of the reasons why the germ-cells of different animals are not all alike with regard to their potentialities of development.[5]

We now come to the question of how the nucleus of the germ-cell acquired its great complexity of structure. We are not concerned here with the origin of the differentiation into nucleus and cytoplasm and the respective parts played by the two in the life of the cell. The problem which we have to consider is the complication introduced by the sexual process, by the periodically recurring union of the germ-cells in pairs, or, as Weismann has termed it, amphimixis. This is well known to be essentially a nuclear phenomenon, in which the so-called chromatin substance is especially concerned, and it is a phenomenon which must have made its appearance at a very early stage of evolution, for it is exhibited in essentially the same manner alike in the higher plants and animals and in unicellular organisms.

Let us suppose, for the sake of argument, that when amphimixis first took place the chromatin of each germ-cell was homogeneous, but that it differed sightly in different germ cells of the same species as a result of exposure to slightly different conditions during its past history. What would be likely to happen when two different samples of chromatin came

[5] Compare Cunningham's "Hormone Theory" of Heredity ("Archiv für Entwicklungsmechanik der Organismen," Bd. xxvi., Heft 3).

together in the zygote? The result would surely depend upon the interaction of the complex colloidal multimolecules of which the chromatin is composed. Various possibilities would arise. (1) The two samples might differ in such a way as to act as poisons to one another, disturbing each other's molecular equilibrium to such an extent that neither could survive. This is possibly what happens when an ovum is fertilised by a spermatozoon of a distinct species, though there are, of course, exceptions. (2) They might be so alike as to be able to amalgamate more or less completely, so that there would simply be an increase of chromatin of possibly more or less modified constitution. (3) They might continue to exist side by side, each maintaining its own individual character.

In the third case the union of the two different samples would give rise to a mass of chromatin of twofold nature, and repetition of the process from generation to generation would, as Weismann has shown, result in ever-increasing heterogeneity, until the chromatin came to consist of a great number of different concrete particles, each of which might conceivably differ from all the others. But when two heterogeneous masses of chromatin meet in the zygote there may be all sorts of mutual attractions and repulsions between the different colloidal multimolecules, for all three of our supposed cases may arise simultaneously, and thus the results may become extremely complicated.

The chromatin of the germ-cells in all existing organisms is undoubtedly heterogeneous, and this heterogeneity may be to some extent visibly expressed in its arrangement in more or less multiform chromosomes during mitosis. We may provisionally accept Weismann's view that these chromosomes are themselves heterogeneous, being composed of chromomeres or ids, which in their turn are composed of determinants.

All this complexity of structure may be attributed to the effects of oft-repeated amphimixis, a view which is supported in the most striking manner by the fact that the nucleus in all ordinary somatic cells (in animals and in the diploid generation of plants) has a double set of chromosomes, one derived from the male and the other from the female parent, and by the well-known phenomenon of chromatin reduction which always precedes amphimixis.

When we approach the problem of heredity from the experimental side we get very strong evidence of the existence in the germ-plasm of definite material substances associated with the inheritance of special characters. Mendelian workers generally speak of these substances as factors, but the conception of factors is evidently closely akin to that of Weismann's hypothetical determinants. The cytological evidence fits in very well with the view that the factors in question may be definite material particles, and it is quite possible that such particles may have a specific chemical constitution to which their effects upon the developing organism are due.

From our point of view the interesting thing is the possibility that arises through the sexual process of the permutation and combination of different factors derived from different lines of descent. A germ-cell may receive additions to its collection of factors or be subject to subtractions therefrom, and in either case the resulting organism may be more or less conspicuously modified.

By applying the method of experimental hybridisation a most fruitful and apparently inexhaustible field of research has been opened up in this direction, in the development of which no one has taken a more active part than the present President of the British Association. There cannot be the slightest doubt that a vast number of characters are inherited in what is called the Mendelian manner, and, as they are capable of being separately inherited and interchanged with others by hybridisation, we are justified in believing that they are separately represented in the germ-cells by special factors. Important as this result is, I believe that at the present time there exists a distinct danger of exaggerating its significance. The fact that many new and apparently permanent combinations of characters may arise through hybridisation, and that the organisms thus produced have all the attributes of what we call distinct species, does not justify us in accepting the grotesque view—as it appears to me—that all species have arisen by crossing, or even the view that the organism is entirely built up of separately transmissible "unit characters."

Bateson tells us that "Baur has for example crossed species so unlike as *Antirrhinum majus* and *molle*, forms differing from each other in almost every feature of organisation." Surely the latter part of this statement cannot be correct, for after all *Antirrhinum majus* and *molle* are both snapdragons, and exhibit all the essential characters of snapdragons.

I think it is a most significant fact that the only characters which appear to be inherited in Mendelian fashion are comparatively trivial features of the organism which must have arisen during the last stages of phylogeny. This is necessarily the case, for any two organisms sufficiently nearly related to be capable of crossing are identical as regards the vast majority of their characters. It is only those few points in which they differ that remain to be experimented on. Moreover, the characters in question appear to be all non-adaptive, having no obvious relation to the environment and no particular value in the struggle for existence. They are clearly what Weismann calls blastogenic characters, originating in the germ-plasm, and are probably identical with the mutations of de Vries. These latter are apparently chromatin-determined characters, for, as Dr. Gates has recently shown in the case of Œnothera, mutation may result from abnormal distribution of the chromosomes in the reduction division.[6]

We have next to inquire whether or not the Mendelian results are really in any way inconsistent with the general theory of evolution outlined in the earlier part of this address. Here we are obviously face to face with the old dispute between epigenesis and preformation. The theory of ontogeny which I first put forward is clearly epigenetic in character, while the theory of unit characters, represented in the germ-cells by separate "factors," is scarcely less clearly a theory of preformation, and of course the conception of definite organ-forming substances in the cytoplasm falls under the same category. The point which I now wish to emphasise is that the ideas of epigenesis and preformation are not inconsistent with one another, and that, as a matter of fact, ontogenetic development is of a dual nature, an epigenesis modified by what is essentially preformation.

We have already dealt briefly with the question of organ-forming substances in the cytoplasm, and it must, I think, be clear that the existence of these is in no way incompatible with a fundamental epigenesis. We shall find directly that the same is true of Mendelian "factors" or Weismannian "determinants."

We have seen that it is possible to conceive of even a complex organism as inheriting nothing from its parent but a minute speck of protoplasm, endowed with potential energy, and a sequence of suitable environments, the interaction between the two bringing about a similar result in each succeeding genera-

6 *Quarterly Journal of Microscopical Science*, vol. lix., p. 557

tion, with a slow progressive evolution due to the operation of the law of accumulation of surplus energy. If any of the conditions of development are changed the result, as manifested in the organisation of the adult, must undergo a corresponding modification. Suppose that the chromatin substance of the zygote is partially modified in molecular constitution, perhaps by the direct action of the environment, as appears to happen in the case of Tower's experiments on mutation in the potato beetle, or by the introduction of a different sample of chromatin from another individual by hybridisation. What is the germ-plasm now going to do? When and how may the changes that have taken place in its constitution be expected to manifest themselves in the developing organism?

Let us consider what would be likely to happen in the first stages of ontogeny. If the germ-plasm had remained unaltered the zygote would have divided into blastomeres under the stimuli of the same conditions, both internal and external, as those under which the corresponding divisions took place in preceding generations. Is the presence of a number of new colloidal multimolecules in the germ-plasm going to prevent this? The answer to this question probably depends partly upon the proportion that the new multimolecules bear to the whole mass, and partly upon the nature of the modification that has taken place. If the existence of the new multimolecules is incompatible with the proper functional activity of the germ-plasm as a whole there is an end of the matter. The organism does not develop. If it is not incompatible we must suppose that the zygote begins its development as before, but that sooner or later the modification of the germ-plasm will manifest itself in the developing organism, in the first instance as a mutation. In cases of hybridisation we may get a mixture in varying degrees of the distinguishing characters of the two parent forms, or we may get complete dominance of one form over the other in the hybrid generation, or we may even get some new form, the result depending on the mutual reactions of the different constituents of the germ-plasm.

The organism into which any zygote develops must be a composite body deriving its blastogenic characters from different sources; but this cannot affect its fundamental structure, for the two parents must have been alike in all essential respects or they could not have interbred, and any important differences in the germ-plasm must be confined to the "factors" for the differentiating characters. The fundamental structure still develops epigenetically on the basis of an essentially similar germ-plasm and under essentially similar conditions as in the case of each of the two parents, and there is no reason to suppose that special "factors" have anything to do with it.

We thus see how new unit characters may be added by mutation and interchanged by hybridisation while the fundamental constitution of the organism remains the same and the epigenetic course of development is not seriously affected. All characters that arise in this way must be regarded, from the point of view of the organism, as chance characters due to chance modifications of the germ-plasm, and they appear to have comparatively little influence upon the course of evolution.

One of the most remarkable features of organic evolution is that it results in the adaptation of the organism to its environment, and for this adaptation mutation and hybridisation utterly fail to account. Of course the argument of natural selection is called in to get over this difficulty. Those organisms which happen to exhibit favourable mutations will survive and hand on their advantages to the next generation, and so on. It has frequently been pointed out that this is not sufficient. Mutations occur in all directions, and the chances of a favourable one arising are extremely remote. Something more is wanted, and this something, it appears to me, is to be found in the direct response of the organism to environmental stimuli at all stages of development, whereby individual adaptation is secured, and this individual adaptation must arise again and again in each succeeding generation. Moreover, the adaptation must, as I pointed out before, tend to be progressive, for each successive generation builds upon a foundation of accumulated experience and has a better start than its predecessors.

Of course natural selection plays its part, as it must in all cases, even in the organic world, and I believe that in many cases—as, for example, in protective resemblance and mimicry—that part has been an extremely important one. But much more important than natural selection appears to me what Baldwin[7] has termed "Functional Selection," selection by the organism itself, out of a number of possible reactions, of just those that are required to meet any emergency. As Baldwin puts it, "It is the organism which secures from all its over-produced movements those which are adaptive and beneficial." Natural selection is here replaced by intelligent selection, for I think we must agree with Jennings[8] that we cannot make a distinction between the higher and the lower organisms in this respect, and that all purposive reactions, or adjustments, are essentially intelligent.

Surely that much-abused philosopher, Lamarck, was not far from the truth when he said, "The production of a new organ in an animal body results from a new requirement which continues to make itself felt, and from a new movement which this requirement begets and maintains."[9] Is not this merely another way of saying that the individual makes adaptive responses to environmental stimuli? Where so many people fall foul of Lamarck is with regard to his belief in the inheritance of acquired characters. But in speaking of acquired characters Lamarck did not refer to such modifications as mutilations; he was obviously talking of the gradual self-adjustment of the organism to its environment.

We are told, of course, that such adjustments will only be preserved so long as the environmental stimuli by which they were originally called for continue to exercise their influence. Those who raise this objection are apt to forget that this is exactly what happens in evolution, and that the *sine qua non* of development is the proper maintenance of the appropriate environment, both internal and external. Natural selection sees to it that the proper conditions are maintained within very narrow limits.

A great deal of the confusion that has arisen with regard to the question of the inheritance of acquired characters is undoubtedly due to the quite unjustifiable limitation of the idea of "inheritance" to which we have accustomed ourselves. The inheritance of the environment is, as I have already said, just as important as the inheritance of the material foundation of the body, and whether or not a newly acquired character will be inherited must depend, usually at any rate, upon whether or not the conditions under which it arose are inherited. It is the fashion nowadays to attach very little importance to somatogenic characters in discussing the problem of evolution. The whole fundamental structure of the body must, however, according to the epigenetic view, be due to the gradual accumulation of characters that arise as the result of the reactions of the organism to its

7 "Development and Evolution" (New York, 1902), p. 87.
8 "Behaviour of the Lower Organisms" (New York, 1906), pp. 334, 335
9 "Histoire naturelle des Animaux sans Vertèbres," tom. i., 1815, p. 185.

environment, and are therefore somatogenic, at any rate in the first instance, though there is reason to believe that some of them may find expression in the germ-cells in the formation of organ-forming substances, and possibly in other ways. Blastogenic characters which actually originate in the germ-cells appear to be of quite secondary importance.

We still have to consider the question, How is it that organic evolution has led to the formation of those more or less well-marked groups of organisms which we call species? We have to note in the first place that there is no unanimity of opinion amongst biologists as to what a species is. Lamarck insisted that nature recognises no such things as species, and a great many people at the present day are, I think, still of the same opinion. In practice, however, every naturalist knows that there are natural groups to which the vast majority of individuals can be assigned without any serious difficulty. Charles Darwin maintained that such groups arose, under the influence of natural selection, through gradual divergent evolution and the extinction of intermediate forms. To-day we are told by de Vries that species originate as mutations which propagate themselves without alteration for a longer or shorter period, and by Lotsy that species originate by crossing of more or less distinct forms, though this latter theory leaves quite unsolved the problem of where the original forms that crossed with one another came from.

I think a little reflection will convince us that the origin of species is a different problem from that of the cause of progressive evolution. We can scarcely doubt, however, that Darwin was right in attributing prime importance to divergent evolution and the disappearance of connecting links. It is obvious that this process must give rise to more or less sharply separated groups of individuals to which the term species may be applied, and that the differences between these species must be attributed ultimately to differences in the response of the organism to differing conditions of the environment. It may be urged that inasmuch as different species are often found living side by side under identical conditions the differences between them cannot have arisen in this way, but we may be quite certain that if we knew enough of their past history we should find that their ancestors had not always lived under identical conditions.

The case of flightless birds on oceanic islands is particularly instructive in this connection. The only satisfactory way of explaining the existence of such birds is by supposing that their ancestors had well-developed wings, by the aid of which they made their way to the islands from some continental area. The conditions of the new environment led to the gradual disuse and consequent degeneration of the wings until they either became useless for flight or, in the case of the moas, completely disappeared. It would be absurd to maintain that any of the existing flightless birds are specifically identical with the ancestral flying forms from which they are descended, and it would, it appears to me, be equally absurd to suppose that the flightless species arose by mutation or by crossing, the same result being produced over and over again on different islands and in different groups of birds. This is clearly a case where the environment has determined the direction of evolution.

In such cases there is not the slightest ground for believing that crossing has had anything whatever to do with the origin of the different groups to which the term species is applied; indeed, the study of island faunas in general indicates very clearly that the *prevention* of crossing, by isolation, has been one of the chief factors in the divergence of lines of descent and the consequent multiplication of species, and Romanes clearly showed that even within the same geographical area an identical result may be produced by mutual sterility, which is the cause, rather than the result, of specific distinction.

Species, then, may clearly arise by divergent evolution under changing conditions of the environment, and may become separated from one another by the extinction of intermediate forms. The environmental stimuli (including, of course, the body as part of its own environment) may, however, act in two different ways: (1) Upon the body itself, at any stage of its development, tending to cause adaptation by individual selection of the most appropriate response; and (2) upon the germ-plasm, causing mutations or sudden changes, sports, in fact, which appear to have no direct relation whatever to the well-being of the organism in which they appear, but to be purely accidental. Such mutations are, of course, inherited, and, inasmuch as the great majority of specific characters appear to have no adaptive significance, it seems likely that mutation has had a great deal to do with the origin of species, though it may have had very little to do with progressive evolution.

Similarly with regard to hybridisation, we know that vast numbers of distinct forms, that breed true, may be produced in this way, but they are simply due to recombinations of mutational characters in the process of amphimixis, and have very little bearing upon the problem of evolution. If we like to call the new groups of individuals that originate thus "species," well and good, but it only means that we give that name, as a matter of convenience, to any group of closely related individuals which are distinguished by recognisable characters from the individuals of all other groups, and which hand on those characters to their descendants so long as the conditions remain the same. This, perhaps, is what we should do, and just as we have learnt to regard individuals as the temporary offspring of a continuous stream of germ-plasm, so we must regard species as the somewhat more permanent but nevertheless temporary offshoots of a continuous line of progressive evolution. Individuals are to species what the germ-plasm is to individuals. One species does not arise from another species, but from certain individuals in that species, and when all the individuals become so specialised as to lose their power of adaptation, then changes in the environment may result in the extinction of that line of descent.

It is scarcely necessary to point out that no explanation that we are able to give regarding the causes of either phylogenetic or ontogenetic evolution can be complete and exhaustive. Science can never hope to get to the bottom of things in any department of knowledge; there is always something remaining beyond our reach. If we are asked why an organism chooses the most appropriate response to any particular stimulus, we may suggest that this is the response that relieves it from further stimulation, but we cannot say how it learns to choose that response at once in preference to all others. If we are asked to account for some particular mutation, we may say that it is due to some modification in the constitution or distribution of the chromosomes in the germ-cells, but even if we knew exactly what that modification was, and could express it in chemical terms, we could not really say why it produces its particular result and no other, any more than the chemist can say why the combination of two gases that he calls oxygen and hydrogen gives rise to a liquid that he calls water.

There is one group of ontogenetic phenomena in particular that seems to defy all attempts at mechanistic interpretation. I refer to the phenomena of

restitution, the power which an organism possesses of restoring the normal condition of the body after it has been violently disturbed by some external agent. The fact that a newt is able to regenerate its limbs over and over again after they have been removed, or that an echinoderm blastula may be cut in half and each half give rise to a perfect larva, is one of the most surprising things in the domain of biological science. We cannot, at present, at any rate, give any satisfactory mechanistic explanation of these facts, and to attribute them to the action of some hypothetical entelechy, after the manner of Prof. Hans Driesch, is simply an admission of our inability to do so. We can only say that in the course of its evolution each organism acquires an individuality or wholeness of its own, and that one of the fundamental properties of living organisms is to maintain that individuality. They are able to do this in a variety of ways, and can sometimes even replace a lost organ out of material quite different from that from which the organ in question is normally developed, as in the case of the regeneration of the lens of the eye from the iris in the newt. That there must be some mechanism involved in such cases is, of course, self-evident, and we know that that mechanism may sometimes go wrong and produce monstrous and unworkable results; but it is, I think, equally evident that the organism must possess some power of directing the course of events, so as generally to secure the appropriate result; and it is just this power of directing chemical and physical processes, and thus employing them in its own interests, that distinguishes a living organism from an inanimate object.

In conclusion I ought, perhaps, to apologise for the somewhat dogmatic tone of my remarks. I must ask you to believe, however, that this does not arise from any desire on my part to dogmatise, but merely from the necessity of compressing what I wished to say into a totally inadequate space. Many years of patient work are still needed before we can hope to solve, even approximately, the problem of organic evolution, but it seemed to me permissible, on the present occasion, to indulge in a general survey of the situation, and see how far it might be possible to reconcile conflicting views and bring together a number of ideas derived from many sources in one consistent theory.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

London.—A course of twelve lectures on the theory and practice of radio-telegraphy will be delivered by Prof. J. A. Fleming at University College, on Wednesdays at 5 p.m., beginning October 28. The course will be in two parts, six lectures before Christmas and six between Christmas and Easter. It is open to both members and non-members of the University. It is intended for telegraphic engineers and electrical students who have already some elementary knowledge of the subject, and it will presume an elementary acquaintance with the differential calculus, and with the properties of vector quantities. The object of the course is to impart a more advanced knowledge of the theory and practice of wireless telegraphy in its modern form. University College is provided with an antenna and P.M.G. licence for its use.

The High Commissioner for New Zealand announces that Dr. W. P. Gowland, of the University of Liverpool, has been appointed to the chair of anatomy at the University of Otago, Dunedin, New Zealand.

We learn from the *Times* that the Senate of the National University of Ireland has passed the following resolution with reference to the destruction of the town of Louvain:—"The Senate of the National University of Ireland desires to offer to the illustrious University of Louvain its deep sympathy on the calamity which has befallen it—a calamity without parallel in history since the destruction of the Library of Alexandria. If this example prevail in warfare, then we may expect to find the records and achievements of civilisation extinguished by ignorance in arms. Therefore we appeal to the universities of all nations to unite in a protest against an act so disastrous to the progress of mankind."

The Board of Agriculture and Fisheries has awarded research scholarships in agricultural and veterinary science of the annual value of 150*l.*, tenable for three years, to the following candidates, viz.:—*Agricultural Science,* J. Ll. Evans (Wales), S. M. Wadham (Cantab.), J. W. Munro (Edinburgh). *Veterinary Science,* R. Daubney, A. H. Adams. The Board has also awarded Mr. E. W. Jeffreys (Wales) an agricultural scholarship tenable for two years to fill a vacancy caused by the resignation of a scholar selected last year. The scholarships have been established in connection with the scheme for the promotion of scientific research in agriculture, for the purposes of which the Treasury have sanctioned grants to the Board from the Development Fund, and they are designed to provide for the training of promising students under suitable supervision with a view to enable them to contribute to the development of agricultural and veterinary science.

The annual report of the Education Branch of the Board of Agriculture on the disposal of grants for agricultural education and research for the year 1913–14 shows that the Board is making satisfactory progress with its comprehensive scheme of organising agricultural work in the country. It has arranged for most of the universities to undertake special work in connection with the various counties which they serve, and, in addition, it supports a number of research institutes put up for the express purpose of investigating particular subjects. The whole scheme has been carefully planned to avoid overlapping; the report furnishes most interesting reading, and is a sufficient reply to the assertion sometimes made that British Government Departments can do nothing for scientific research. It is not claimed that the scheme is yet perfect; indeed, it is not yet in full working order, but it seems clear from the details furnished that things are going satisfactorily, and that the fully developed scheme will serve the purpose for which it was intended. Provision is made for higher agricultural education, the provision of technical advice for farmers, the investigation of local problems, and for carrying out agricultural research at institutions the function of which it is to develop subjects rather than to study set problems. The total amount of money granted during the year was 67,939*l.*, against 32,434*l.* last year.

The calendar for 1914–15 of the Edinburgh and East of Scotland College of Agriculture has now been issued, and copies may be obtained from the secretary to the college, 13 George Square, Edinburgh. The college was founded in 1901 with the object of providing for agricultural education and research in the central and south-eastern counties of Scotland. The classes of the college are arranged in conjunction with certain classes in the science faculty of Edinburgh University, so as to provide a full course of teaching theoretical and practical, in agriculture and the allied sciences. This cooperation with the University has the further advantage that the courses for the diploma

of the college and for the degree of B.Sc. of the University are concurrent. The calendar gives to intending students full guidance as to the curricula for the B.Sc. degree in agriculture and in forestry, the college diploma in agriculture, and the college certificate in horticulture. Particulars are also given of shorter courses which may be taken by those who are unable to spare time for sufficient attendance to gain the qualifications mentioned. Notes are included as to the locality and objects of the numerous experiments and demonstrations which are carried on in the grounds of the college. These are of special interest to the practical farmer, who is invited to consult the college staff in regard to his individual problems.

ADMIRAL SIR CYPRIAN BRIDGE, in a letter to the *Times* of August 29, comments on the notices published by the Vice-Chancellors of various universities announcing that due attention will be paid to the academic interests of students who have gone or are going to share in the defence of the country. The surprising thing, he says, is that university authorities should not have found themselves obliged to announce that as all their undergraduates above nineteen years of age and physically fit had joined the fighting forces of the Crown, their universities would be virtually empty until the need for fighting men was satisfied. Dr. A. E. Shipley, master of Christ's College, Cambridge, in a succeeding issue of our contemporary, points out that at Cambridge a considerable number will be left behind who are precluded by their age, physique, or physical condition from joining the forces. There are also foreigners in residence—sons of our allies—and it is hoped there will be more of these who, unfitted to fight, wish to continue their education. Dr. Shipley goes on to warn the public that all the young men who are not as yet in the Army or Navy are not shirkers. Some are not eligible for one reason or another, but are as anxious to serve their country as any man at the front. It is possible for zeal to outstrip justice and charity. Other correspondents point out that in the newer universities, half, or more than half, of the students are under the age of nineteen, and many are women. It is believed that in Oxford the number of undergraduates in residence next term will be reduced by about one-half, and that every university will provide large contingents of the Officers Training Corps for the service of the country.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 17.—M. P. Appell in the chair.—A. **Lacroix**: The non-volcanic basic rocks of Madagascar. The mineralogical and chemical composition of the basic rocks are dealt with in the present communication. Complete chemical analyses of twenty-two rocks are given.—Otto **Scheuer**: The action of the radium emanation upon detonating gas. The combination of hydrogen and oxygen is rapidly brought about by the radium emanation; in one experiment the mixture exploded. Both water and hydrogen peroxide are produced during the reaction, and it is probable that the latter is the primary product.—A. **Werner**: The optical activity of chemical compounds not containing carbon. An account of the preparation of the cobalt-amine salt, $[Co(OH)_2.Co(NH_3)_4]_3Br_6+2H_2O$, not containing carbon and possessing a specific rotatory power. The aqueous solution becomes inactive after two hours.—Paul **Pascal**: The rôle of valency in the additivity of diamagnetism.—N. A. **Barbieri**: The proximate analysis of wheat.—Gabriel **Bertrand** and Arthur **Compton**: A modification of amygdalinase and amygdalase due to age. Under the influence of time amygdalinase and amygdalase extracted from almonds lose their diastatic activity very slowly. The concentration of hydrogen ions most favourable to diastatic action increases with age.

CAPE TOWN.

Royal Society of South Africa, July 15.—Dr. L. Péringuey, president, in the chair.—L. **Péringuey**: Note on Palæolithic implements of large size found in the precincts of Cape Town city. The palæoliths are mostly of very large size and made of slate indurated by contact with the granite. They were discovered on the lower part of the talus of Signal Hill, within stone-throw of the houses built in this locality. It may be contended that natural agencies could have produced this amygdaloid form were it not for a few examples of "bouchers" found contiguously, and in which the artefact is patent. The locality is about 350 feet from the raised beach ledge which is now Green Point Common. These raised beaches will probably prove the means of obtaining ultimately a key to the age of many of the present geological features.—L. **Péringuey**: Note on grooved stone slabs, used by the Strand-Looper-San aboriginals. Search in undisturbed kitchen-midden deposits found so numerously within a sixty-mile radius of the littoral of the Union, seldom fails to reveal the presence of flat stones having a shallow artificial depression in the centre. Nor are these stones always restricted to this area. The depression is often found on each side. Speculations as to their having been used for sharpening blades of assegais or similar weapons are of course untenable. More likely was the theory of the stone having been utilised as a cooking-stone, the depression to receive the gravy.—K. H. **Barnard**: Exhibition of maine invertebrates. The discovery of the Siliceous sponge, *Regadrella phœnix*, from the deep water off East London, fills a gap in the hitherto known distribution of the species. *Aega monophthalma* and *Epimeria cornigera* were recorded for the first time in the southern hemisphere, a fact which bears on the theory of bipolarity.—E. J. **Goddard**: On the anatomy of *Ozobranchus branchiatus* and its position in the class Hirudinea. The paper deals with the somitic constitution and anatomy of *Ozobranchus branchiatus*, which must be one of the earliest forms of marine life taken in the Pacific Ocean. The species is, in addition to its historic interest, of significance in regard to its constitution, since it supports the suggestion previously made by the author, namely, that the Hirudinea and Arthropoda have been evolved from a common ancestor.—Paul A. van der **Bijl**: Preliminary investigation of the deterioration of maize infected with *Diplodia zeae* (Schw.) Lev. Maize infected with *Diplodia zeae* has a higher acidity than healthy maize. Infected maize gives Ori's reaction distinctly; it has a higher percentage of ash and of nitrogen.

CALCUTTA.

Asiatic Society of Bengal, August 5.—H. H. **Hayden**: Note on the application of the principle of isostatic compensation to the conditions prevailing beneath the Indo-Gangetic alluvium. This note has been written in reply to certain criticisms made by Col. G. P. Lenox Conyngham in "Records of the Survey of India," vol. v., on a paper published by the author in the "Records of the Geological Survey of India," vol. xliii., part 2, in which he discusses the evidence for a rift 20 miles deep extending all along the foot of or even under the Himalayas. The existence of such a rift was postulated by Col. Burrard to explain the anomalies observed in the deflection of the plumb line at certain stations in the Himalayas and in the plains south of them. The author reiterates his desire to reconcile the geodetic facts with the generally

accepted theories as to the character of the alluvial depression south of the Himalayas—*i.e.*, a wedge-shaped mass with its thick end against the foot of the Himalayas shallowing to zero against the older rocks of the Peninsula—without discarding Dutton's theory of isostasy. He therefore endeavoured to show that by assuming other depths for complete isostatic compensation for India than 113·7 km.—that which Hayford had found to hold generally in the United States, the geodetic anomalies could be more easily explained, provided one was prepared to admit the possibility of the depth of isostatic compensation not being constant throughout the world. Reference is made to a recent paper by Mr. R. D. Oldham claiming to have proved by calculation that such a wedge-shaped trough filled with alluvium would be capable of producing just the observed anomalies, so that Col. Burrard's rift hypothesis becomes superfluous.—Barun Chandra **Dutt** and Surya Narayan **Sen**: Action of nitric oxide on metallic peroxides suspended in water. Part i. The authors have studied the action of nitric oxide on lead peroxide and barium peroxide suspended in water. They conclude from their experiments that in the case of lead peroxide both lead nitrite and lead nitrate are formed, whilst in the case of barium peroxide the only product of the reaction is barium nitrite. Experimental evidence is adduced to show that during the formation of the nitrite and nitrate of lead part of the lead peroxide is reduced to monoxide, and that lead nitrate is formed by the oxidizing action of lead peroxide on lead nitrate.—J. Sykes **Gamble**: Materials for a flora of the Malayan Peninsula No. 25. This part contains the families Nos. 96 (*bis*) Cytinaceæ and 109 Balanophoraceæ, both by Mr. H. N. Ridley; also Nos. 112 Juglandaceæ, 113 Myricaceæ, 114 Casuarinaceæ, 115 Fagaceæ, and 116 Salicaceæ, all by Mr. Gamble. In these seven families there are eleven genera and sixty-five species, of which one species in Balanophoraceæ, and eight in Fagaceæ are new. The new species have been described, with the usual Latin diagnoses, in the Kew Bulletin.—H. H. **Mann** and N. V. **Kanitkar**: Notes on the fat of *Garcinia indica*, the so-called Kokam butter. The present note supplements the information contained in D. Hooper's paper on the fats of Garcinia species (Journal, Asiatic Society of Bengal, vol. iii., page 257, published in 1907), but confines itself to Kokam butter, which is the fat of *Garcinia indica*. As already noted by Heise and Hooper, the fat is mainly oleo-distearin. The volatile fatty acids are a mixture of acetic and propisnic acids in practically equal proportions; butyric acid is absent.

THE WAR—AND AFTER.

THE terrible war which is now raging, not only near our shores, but also much further afield, is teaching us many lessons, among them that the things which make most for a nation's life are apt not to be considered by the partisans of party politics. But it also shows that the British nation is sound enough at heart to throw off the trammels of party politics when a supreme moment arrives. Such a supreme moment is now on us and Britain is struggling for life with a foe who now shows his true colours. Many of us have been great admirers of Germany and German achievements along many lines, but we have now learned that her "culture" and admirable organisation have not been acquired, as we do not doubt was thought by the workers themselves, for the purpose of advancing knowledge and civilisation, but, in continuation of a settled policy, they have been fostered and used in order that a military caste in Germany, with the Kaiser at its head, shall ride roughshod over Europe, all treaties and national rights abrogated, all conventions set aside, all honour thrown to the winds, all laws of war and even of humanity disregarded. We are back in the days of the Huns. There is no doubt that in the complete plan of the great schemer the conquest and subsequent effacement of Britain were included.

Thank God, after many days of the most terrible fighting which the world has ever seen, it seems as if the day of the humiliation of France, which was to be the first stepping-stone to the final achievement, is not yet, and that before long the arch-plotter may be caught in the toils which he set for others. His final humiliation and overthrow are necessary for the world's peace, and will certainly come.

It is not for a scientific journal to chronicle the progress or to predict in detail the possible consequences of a war so brutally brought about, so brutally carried on by our enemy. Our task rather is to point out the importance not only of strengthening the troops in the field, but of seeing that our industries shall not suffer too greatly, for industry can alone supply in the long run the sinews of war for whatever period the conflict lasts; industry, moreover, to be most effective, must be broadly based on science.

In the latter direction the Government has taken a very wise step. The following communication has been issued from Downing Street:—

"Bearing in mind the sudden cessation of the oversea trade with Germany and Austria, the Secretary of State for the Colonies, with a view to alleviating to some extent the loss of business and employment both in the United Kingdom and the Colonies, telegraphed on the 15th inst. to some of the more important colonies not possessing responsible government to remind them that it is of the utmost importance to have full information up to date respecting the principal imports into each colony from Germany and Austria and as to the products of each colony hitherto exported to those countries. The Secretary of State has further desired that he should have by the earliest opportunity particulars as to the leading lines of articles of trade with Germany and Austria, illustrated by samples in the same way as was arranged in 1895.

"The Secretary of State has it in mind that action on the above lines will not only be an immediate benefit as regards employment in the United Kingdom, but should also lead to the permanent advantage of British trade in general.

"It is understood that the Trade Commissioners in the various self-governing Dominions are already kept closely in touch with the requirements of the trade in those Dominions, and collections of samples of different lines of goods in which British manufacturers might compete have recently been sent, or are on their way from certain parts of those Dominions.

"As regards neutral foreign countries the Secretary of State for Foreign Affairs has undertaken to send a similar request to his Majesty's Consuls in all places where such an inquiry is likely to have a useful result.

"The present intention of the Secretary of State for the Colonies is that, as soon as the samples from different parts of the Empire and from neutral countries are collected the traders and manufacturers of the United Kingdom shall have an opportunity of inspecting them in a central exhibition, possibly at the Imperial Institute. At any rate, no time will be lost in making suitable arrangements to carry out this intention."

"The Board of Trade are moving on the same lines, and have devised what promises to be a fruitful campaign for assisting British manufacturers and traders to take advantage of the war by establishing themselves, in neutral as well as Colonial markets, in those branches of business which have hitherto been largely in the hands of their German, Austrian, and Hungarian rivals.

"There are two great and undoubted factors which tend to ensure such a development of British Overseas trade to a very considerable extent. One is to be found in the safety of the trade routes, together with the protection afforded by the State scheme of insurance against war risks, and the financial measures also taken by the Government for the continuance of business transactions. The second is that German and Austro-Hungarian trade with foreign countries is at a standstill.

"In pursuance of this scheme the Commercial Intelligence Branch of the Board of Trade (73 Basinghall Street, E.C.) are issuing to manufacturers and merchants, trade associations and chambers of commerce, monographs giving information with regard to possible foreign and Colonial developments in certain important trades carried on by them or in their respective districts. The trades dealt with in the first series of monographs are cutlery, iron and steel wire, hollow-ware (enamelled or tinned), woollen and worsted piece goods, and cotton hosiery (stockings and socks)."

To those who have followed the German "culture" for the last thirty or forty years it is well known that the fostering of their industries in that country by technical instruction in all forms has been increasing, and it will be found that our manufacturers will have the greatest difficulty in carrying out the Government's intention precisely in those branches of industry in which technical instruction of the most advanced kind, with accompanying research, has been most lacking in Britain.

For some time before the war a committee of the British Science Guild was preparing a statement showing the disadvantages under which the optical trades suffer in this country, and we are glad to see that the President of the Board of Trade has now appointed a committee "to consider and advise as to the best means of obtaining for the use of British industry sufficient supplies of chemical products, colours, and dye-stuffs of kinds hitherto largely imported from countries with which we are at present at war." Of this Committee Lord Haldane is chairman, and Dr. Beilby and Profs. Meldola and Perkin are among the members.

Let us hope that these and other similar efforts will be fruitful of result. Let us increase our "culture," not as part of a settled plan for the detriment of other countries, but as a serious endeavour to advance our own Empire and modern civilisation generally with all that it brings with it.

BIOLOGY OF THE SEX- AND BLOOD-CELLS.

(1) *Artificial Parthenogenesis and Fertilisation.* By Jacques Loeb. Originally translated from the German by W. O. Redman King. Supplemented and revised by the Author. Pp. x + 306. (Chicago: University of Chicago Press; London: Cambridge University Press, n.d.) Price 10*s.* net.

(2) *The Biology of the Blood-cells. With a Glossary of Haematological Terms.* By Dr. O. C. Gruner. Pp. xii + 392 + plates. (Bristol: John Wright and Sons, Ltd., 1913.) Price 21*s.* net.

(1) THE development of the female cell or egg without fertilisation by the male cell or sperm—parthenogenesis—has been known to occur among the plant lice, or aphides, since the eighteenth century, but the artificial production of a similar phenomenon—artificial parthenogenesis—is essentially an accomplishment of the closing decades of the nineteenth century. This book gives an excellent and fascinating summary of the considerable amount of experimental work which has now been performed on this subject. Artificial parthenogenesis has been principally carried out with the eggs of sea-urchins, but the same kind of results have also been obtained with those of starfish, annelid worms and molluscs, and also with frogs and toads. Although there is usually considerable mortality among the artificially fertilised forms during the earlier periods of development, Delage has reared two parthenogenetic larvæ of the sea-urchin during sixteen months to a stage of sexual maturity, and Loeb and Bancroft raised tadpoles, and even a young frog with eggs in the sex-glands, from artificially fertilised frogs' eggs!

Commencing with some general remarks on the morphology of development, the influences of oxidation and of membrane formation on the development of the fertilised egg are considered. Apparently oxygen is necessary for development, and all observations point to the conclusion that the processes determining or underlying nuclear division depend upon oxidation. While a certain amount of oxidation proceeds in the unfertilised egg (and ultimately leads to its disintegration and death), the essential effect of the entrance of the sperm seems to be an acceleration, it may be to six-fold, of the oxidation processes, and if fertilised eggs be deprived of all oxygen no nuclear or cell division occurs; other reactions, such as hydrolyses, also doubtless take place. Another result of fertilisation is the immediate formation of a membrane, the fertilisation membrane, which surrounds the egg, after which the chemical processes that underlie development ensue.

The earlier successful attempts to induce artificially the development of sea-urchin eggs were obtained by the use of hypertonic sea-water (100 c.c. sea water + 2 grams sodium chloride). The eggs are first soaked in the hypertonic solution for 2–4 hours, and are then returned to ordinary sea-water; if allowed to remain in th

hypertonic solution no development takes place. Other hypertonic solutions, provided they possess a similar osmotic action and are not poisonous (as is the case, for instance, with copper salts), may also be used. Better methods have since been devised, *e.g.* treatment first with a fatty acid, such as butyric, then with sea-water, next with the hypertonic solution and finally removal to sea-water. The fatty acid initiates membrane formation, the hypertonic solution the oxidation processes. Various substances, such as saponin, which have a lytic or solvent action upon the cortical layer of the egg and therefore lead to membrane formation, can also be substituted for fatty acid.

Another fact of considerable interest is that blood or tissue-extracts, or the dead or living sperm, of a *foreign* species will induce membrane formation in the unfertilised sea-urchin egg, while the extracts of the sea-urchin itself are inefficient to do so and the *living* sperm is alone effectual. This appears to be due to the fact that the foreign materials can diffuse into the egg, while its own materials are unable to, but must be carried by the *living* sperm. Various questions connected with heredity are discussed, and finally a chapter deals with the interesting question—can an embryo develop from a sperm? Apparently in yolk and white of egg, fowl sperm can undergo transformation into a nucleus, but we are not yet in a position to state that the sperm can undergo mitosis outside the egg. Altogether this book can be recommended as an authoritative statement on artificial parthenogenesis by one who has himself contributed so much to the subject.

(2) Comparatively simple as the structure of the blood seems at first sight to be, the more it is studied the more complex it becomes, and the literature dealing with this subject has now become truly enormous. In the present volume the author has attempted to summarise the researches that have been carried out on the structure, functions, and origin of the various elements of the blood, both normal and abnormal, which make their appearance in cases of disease. On the whole we think the author has accomplished his object, and has produced a reference book which will be very useful to those who are working at this subject. A bibliography, a glossary of hæmatological terms (which runs into more than thirty pages), and indexes to subjects and to authors, complete a work which must have entailed a considerable amount of labour.

R. T. H.

MATHEMATICAL TEXT-BOOKS.

(1) (*a*) *Plane and Solid Geometry.* By Prof. W. B. Ford and C. Ammerman. Edited by E. R. Hedrick. Pp. ix+321+xxxiii. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1913.) Price 5*s.* 6*d.* net.

(*b*) *Solid Geometry.* By Prof. W. B. Ford and C. Ammerman. Edited by E. R. Hedrick. Pp. ix+215–321+xlix. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1913.) Price 3*s.* 6*d.* net.

(2) *A School Course in Geometry.* By W. J. Dobbs. Pp. xxii+427. (London: Longmans, Green and Co., 1913.) Price 3*s.* 6*d.*

(3) *Analytic Geometry and Principles of Algebra.* By Prof. A. Ziwet and L. A. Hopkins. Pp. viii+369. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1913.) Price 7*s.* net.

(4) *Slide-Rule Notes.* By Colonel H. C. Dunlop and C. S. Jackson. Pp. 127. (London: Longmans, Green and Co., 1913.) Price 2*s.* 6*d.* net.

(5) *A First Numerical Trigonometry.* By W. G. Borchardt and the Rev. A. D. Perrott. Pp. xi+159+xvii+xvii. (London: G. Bell and Sons, Ltd., 1913.) Price 2*s.* 6*d.*

(6) *Elementary Graphic Statics.* By J. T. Wight. Pp. xii+227. (London: Whittaker and Co., 1913.) Price 4*s.* net.

(7) *Models to Illustrate the Foundations of Mathematics.* By C. Elliott. Pp. viii+116. (Edinburgh: Lindsay and Co., 1914.) Price 2*s.* 6*d.* net.

(8) *Exercises in Mathematics.* By D. B. Mair. Pp. xi+469. (London: Macmillan and Co., Ltd., 1914.) Price 4*s.* 6*d.*

(9) *A School Statics.* By G. W. Brewster and C. J. L. Wagstaff. Pp. viii+248. (Cambridge: Heffer and Sons, Ltd., 1913.) Price 3*s.* net.

(10) *Proceedings of the London Mathematical Society.* Second series. Vol. xii. Pp. lix+488. (London: Francis Hodgson, 1913.)

(1) IN America, as in England, the teaching of geometry has altered recently both in method and scope; and these changes are indicated in the report of the committee of the National Education Association, the recommendations of which have been in the main adopted by the authors of this volume. The limitations of the subject-matter are similar to those with which English students are familiar, but there is a marked difference in the arrangement. The treatment of areas is postponed nearly to the end of the course, thus enabling angle and

tangent properties of the circle and theorems in proportion and similarity, to be taken at an early stage.

The course of solid geometry, which occupies about one-third of the volume, and can also be obtained separately, follows the usual lines. There are three sections: (1) lines and planes in space; (2) polyhedra, cylinders, cones; (3) the sphere, the latter being treated more fully than usual. The examples are less conventional and more interesting than those in the ordinary text-book.

(2) The author holds very strongly that pure geometry should not be separated from other branches of mathematics. In a single volume he has included quite a considerable amount of trigonometry, calculus, and analytical methods (solid geometry is reserved for a second volume); and he has attempted to shew how all these subjects should be combined together, each assisting the development of the other. If proofs of geometrical properties can be simplified by the use either of trigonometry or analysis, he maintains that not only is it legitimate to do so, but that it is definitely wrong to ignore this opportunity. Mr. Dobbs's book should exercise a refreshing influence on educational methods.

(3) Into the ordinary analytical course a certain number of sections on pure algebra have been introduced on the ground that their utility can best be explained in this connection. This certainly justifies the inclusion of simultaneous equations, theory of equations, complex numbers, gradients, and determinants; the brief account, however, of permutations and combinations in connection with the latter seems somewhat irrelevant. The examples are of a numerical character, and advanced geometry of the conic is left aside. Special mention must be made of an interesting section on higher plane curves and empirical equations. The last four chapters cover the usual course of solid geometry so far as quadrics referred to principal axes.

(4) Mr. Jackson's name is in itself a sufficient guarantee that students will find all that they can possibly require in this account of the use of the slide-rule. After a brief introduction there are successive chapters on proportion, evolution and involution, the solution of quadratic and cubic equations, the trigonometric and logologarithmic scales, the plotting of curves and errors. The reader must of course have a slide-rule in his hand, but the clearness of the diagrams from which all superfluous markings have been omitted will make his task easy.

(5) This book is designed for the junior forms of secondary schools, in view of the fact that trigonometry is now given an early place in the curriculum. The examples are therefore of a simple character; radian measure is postponed to the last chapter, and identities and compound angles are excluded. We think that an unnecessary amount of space has been devoted to logarithms; all modern text-books on arithmetic and algebra contain chapters on this subject, and its repetition here is a survival from the times when only seven-figure tables were used. There is a first-rate set of test-papers at the end of the book.

(6) This is a book for the practical engineer, but it contains many problems that might usefully be set to the mathematical specialist. No previous knowledge of mechanics and only the elements of algebra are required. After a clear discussion of resolution and composition, the triangle of forces and Bow's notation, various problems of the crane are considered. The graphical theory of moments, bending moments, and shearing forces is then described, and applications are made to dead and rolling loads, symmetrical and unsymmetrical roof loadings, wind pressure, walls withstanding pressure, centre of gravity and moments of inertia. The author has succeeded in compressing into a comparatively small compass a great deal of valuable matter. There is, of course, naturally nothing that is original, but the contents are just what the ordinary engineering student most needs.

(7) The purpose of this tract is to advocate the introduction of some account of modern views upon the foundations of mathematics into elementary work. It is claimed that by a judicious use of models an insight can be gained fairly easily into the root ideas of mathematical philosophy, and that by a method which involves only an extension or rearrangement of the practical work now being done at school. The ideas here dealt with are correspondence, class, classification, multiplexes, etc. We cannot think this is suitable for the ordinary boy: however simple the illustrations may be, he will almost certainly fail to carry away with him anything he can himself regard—and that is in itself of very great importance—as real knowledge.

(8) Every teacher should possess this book; the exercises cover the course of arithmetic, algebra, geometry, and trigonometry taken by the non-specialist, and may be used either for revision or to supplement at a first reading the ordinary text-book. Some of the sections are headed by a note recommending their omission if not required for examination purposes. Apart from these, the questions are so chosen as to test the intelligence of the student, to illustrate the utility of the

subject, and exhibit its practical bearing. It is the best collection of mathematical examples we have yet met.

(9) Now that an experimental course of statics has obtained a firm foothold in the school curriculum, it is possible to introduce boys of no special mathematical talent to certain features of theoretical work. In addition to the elements of geometry and algebra, nothing more than a knowledge of the trigonometry of the right-angled triangle is needed for applications of all the fundamental ideas which make this subject educationally valuable.

The volume before us contains just what is needed for work of this character. It opens with the use of pulleys and the ideas of work, power, velocity-ratio, and efficiency. Then follow simple cases of moments and applications to the more important machines. In this way the student is led at once to see the practical utility of the work, and is able by experiment to clarify his conception of force, etc. No use is made of the parallelogram and triangle of forces until comparatively late in the course, and formal bookwork proofs are postponed to the end. The examples are chosen so as to illustrate the principles of mechanics rather than to test the student's analytical ability.

(10) We are glad of this opportunity of directing attention to the work that is being done by the London Mathematical Society. All those who are interested in any branch of higher mathematics, whether they hope or intend to do any research work or not, should apply for election. Only in this way is it possible for students to keep in touch with the trend of modern developments when their University days are over.

OUR BOOKSHELF.

British Rainfall, 1913. Compiled under the direction of H. R. Mill. By R. C. Mossman and C. Salter. Fifty-third annual volume. Pp. 92+384. (London: E. Stanford, Ltd., 1914.) Price 10*s.*

THIS valuable publication is well known to readers of NATURE, having been frequently referred to in its columns. The fundamental part of the work includes: (1) general tables of total rainfall, and (2) observers' remarks on the weather; these are of great interest, and refer mostly to exceptional phenomena. The discussion of the data deals *inter alia* with monthly and seasonal rainfall, heavy daily falls, and the relation of the annual rainfall to the average. A great rainstorm of September 17, which was most intense near Doncaster, is illustrated by a coloured plate; the area with more than an inch of rain in about fourteen hours comprised more than 1300 square miles. The rainfall of the year over the whole of the British Isles was almost exactly equal to the average of thirty-five years (1875–1909). The excess in Wales was 9 per cent. and in Ireland 7 per cent.; elsewhere there was, generally speaking, a deficiency. The volume includes three special articles: (1) an appreciative memoir of the late Sir John Murray, who represented Scotland on the Board of Trustees of the British Rainfall Organisation; (2) the dry summer of 1913—in July and August the rainfall deficiency was 60 per cent. over the United Kingdom as a whole; (3) frequency of heavy rains in short periods, 1868–1913. The useful work of the organisation is dependent upon voluntary contributions, but unfortunately it is not self-supporting; the director has to meet considerable deficiencies, consequently application for Government aid has become necessary.

Handbook of Photomicrography. By H. Lloyd Hind and W. Brough Randles. Pp. xii+292+44 plates. (London: George Routledge and Sons, Ltd., n.d.) Price 7*s.* 6*d.* net.

THIS book gives a useful and adequate account of the theory and practice of photomicrography. It is written from the point of view of the beginner and amateur, and full explanations are given of the principles governing the results aimed at and of the methods for obtaining these results. Photomicrography with the lowest and highest powers is dealt with, and wherever possible simple and home-made apparatus is described. In addition to photomicrography proper, the various photographic processes are explained and described, and methods of making lantern slides, colour photography, and the preparation and mounting of objects are included. The book is well produced and profusely illustrated both by figures in the text and with forty-four plates, several of which are coloured and reproduced from direct colour photographs. The plates illustrate very well the different results that can be obtained with different methods of illumination, various objectives and varying adjustments. We believe that Messrs. Hind and Randle's handbook will be found a very useful work on the subject of photomicrography.

The Microscopy of Drinking Water. By Prof. G. C. Whipple. Third edition, rewritten and enlarged. Pp xxi+409+xix coloured plates. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 17*s.* net.

WE are glad to welcome the third edition of this valuable book. Since the first edition was issued in 1880 an enormous amount of work has been devoted to the study of the microscopic organisms in water, and the increase in size of the present edition bears witness to this. The mystery of the comings and goings of various groups of algæ and protozoa in our lakes and reservoirs still, however, remains unsolved. From the practical side much progress has been made in the artificial means of controlling Plankton growths and the purification of waters containing them.

The first part of the book has been almost rewritten, and contains chapters on copper treatment for eradication of algæ, the soil-stripping of

reservoir sites and the use of the microscope and photomicrography. The latter portion of the book, containing descriptions of various groups of water-organisms, has also been revised, and the plates showing the commoner organisms of water have been printed in colours, making identification easier.

The book is one which should find a place in every bacteriological and public health laboratory and in the office of the water-engineer.

R. T. HEWLETT.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Micromillimetres and Micromicrons.

IT is very desirable that men of science should adhere to the conventions which have been established with regard to the use of the terms employed for units in the metric system. It has been generally agreed that the prefixes mega- and micro- should indicate the multiplication and division respectively by a million of the unit expressed by the term they precede. In this way a micrometre usually shortened to *micron*, means a millionth part of a metre, or, in other words, a thousandth of a millimetre; and a *micromillimetre* signifies a millionth part of a millimetre, or, what is the same thing, a thousandth part of a micron. It is, therefore, to be regretted that in the translation, published in Geneva, by L. Duparc and Vera de Dervies, of Nikitin's excellent account of Fedorov's "universal" method of microscopical mineral research we find the term *micromicron* employed in place of micromillimetre. The former term should mean a millionth part of a micron—that is to say, a metre $\times 10^{-12}$, a unit that might be usefully employed in expressing intermolecular or interatomic distances in crystals, which we are now at last in a position to determine in many cases.

JOHN W. EVANS.

Imperial College of Science, South Kensington, September 3.

Origin of Species.

IN Darwin's great work on this subject he claims that Dean Herbert, in 1822 and 1837, held that "single species of each genus were created in an originally highly plastic condition, and that these have produced, chiefly by intercrossing, but likewise by variation, all our existing species."

Years of study along this line have assured me that he was right. I am now especially interested as I have a few trees on hand which seem to prove this position. They are a cross between Quercus and Juglans, which bears walnut-like nuts on a tree which bears oak-like leaves: at least a new species and perhaps a new genus. If this tree had been found in the forest it would have caused no remarks, but originating in the garden it has become the wonder of the world. Here is an oak tree in appearance which bears perfect walnuts, all originated in one year and fairly productive and fixed.

This tree gives me further evidence of the fact that all sexual life known to us, both animal and vegetable, has sprung from hybrids.

NEWTON B. PIERCE.

Pacific Coast Laboratory and Wild Plant Improvement Gardens, Santa Ana, California.

LECTURES ON THE ANIMAL KINGDOM BY LINNÆUS.[1]

IT is probable that most modern zoologists, when unfamiliar with the Scandinavian tongues, know little of the zoological writings of Linnæus beyond the "Systema Naturæ," and that from this restricted evidence they draw the natural but entirely erroneous conclusion that, considered as a zoologist, Linnæus was little more than a methodical compiler, classifier, and name-giver. If, moreover, the modern zoologist is not so well acquainted with the history of his science as he should be, he is apt to seize rather on the defects, or even absurdities, in the "Systema" as compared with his own knowledge, and to ignore the real advances made by the great Swede over the attempts of his predecessors. There are, as we have hinted, many writings by Linnæus that prove the falsity of such opinions, and now another has just been issued by the University of Uppsala which enables one to read between the lines of the "Systema," and to realise the wide zoological knowledge and still more the philosophy and humanity on which it is based. The volume consists of a complete course of lectures on the animal kingdom, delivered by Linnæus between 1748 and 1752, and collected from the notes made by various pupils, of which more than forty manuscripts are preserved in the university library. The collation of these manuscripts was begun by the late Dr. M. B. Swederus, and has been completed by Dr. Einar Lönnberg, with the help of Miss Greta Ekelöf. The lectures are followed by a detailed commentary and by short accounts of 123 authors quoted by Linnæus; these two parts are by Dr. Lönnberg, who has availed himself of the help of various colleagues, living and dead.

And now of Linnæus as a lecturer, what may we think? Approaching him at second-hand, and without the magic of his enthusiastic presence, we yet see how he infused a living and practical interest into what might so easily have been a dry catalogue of species. An undergraduate's notebook omits much that the writer does not consider essential, the humorous asides, the occasional divagations, the purple patches; but the students of Uppsala realised that they listened to no ordinary man, and it is clear that much has been taken down verbatim. Certainly, that must be the case with the stately Prolegomena, which we should like to have translated in full, but must at least make some attempt to abstract:—

Generation after generation of earthly creatures comes into being only to pass into nothingness. And yet, though fashioned only for vanity, each creature struggles to preserve its life; one preys upon another so that nature is a *bellum omnium perpetuum in omnes*, and of all creatures man is most inhuman. And yet man, with his works of wisdom, his castles and towers, comes only to dust. What is the object of so vain a contrivance? The answer is given by natural history.

[1] Linnés Föreläsningar öfver Djurriket, med understöd af Svenska Staten för Uppsala Universitet utgifna och försedda med förklarande anmärkningar af Einar Lönnberg. (Uppsala, 1913.)

Particles of stone build up the mountains, and these, again, break down into stones and sand. But on this live the plants, each springing from a tiny seed, and growing from mould, with a little water and air, to such a wonder-work as all the artists of the world cannot rival. They bloom and seed and perish, but meanwhile they shelter and give food to all kinds of animals. And the animals, they too spring each from a little seed; and earth, air, and water are compounded to form that masterpiece which every animal is. Yet the animals feed, not on mould, but on the plants; and all animals in their turn serve the needs, the nourishment, or the pleasure of mankind. And so comes the conclusion: all is fashioned for the sake of man. Earth, herb, beast, and man; further the metamorphosis cannot go. But why is this great world created for man? Is not he, too, a thing of naught? What mighty attributes has he? This, this is his peculiar property: that not only can he see, hear, smell, taste, feel things, but that he can also contemplate the marvellous construction of all natural bodies, fathom their peculiar qualities, and reason therefrom to their high and skilful Master.

Love of life forces every creature to seek the necessaries of life. Man goes out with the rest, and so he must note and admire the work of the Creator. Some rich men, indeed, with all needs ready supplied, are little better than savages who sit in the sun and let fruit drop into their mouths; but the poor, who must earn food with toil and sweat, learn better to thank God therefor.

The true inquirer into nature's works must observe with accurate attention, seek out origins, follow generation and growth, unravel use and harm, and finally note change and decay. He looks not on the rowan-berry with the eyes of the raven, tastes not the herbs with the tongue of an ox, nor sports with doves after the manner of the hawk. Not hastily, not upon one or even upon many journeys, but ceaselessly and diligently must the inquirer mark and ponder on the natures and causes of things, on their relations both to themselves and to their surroundings, seeing that no natural thing lives or dies to itself alone.

Some object that natural history is but a heap of useless names. True, to know a heap of names and nothing more is no learning. But it were as easy to become a scholar without the alphabet, as a naturalist without names. Describe me a thing precisely as you will, I can make no use of it without a name; only by names can such knowledge be passed on, since the object cannot always accompany the description. Names are the alphabet of natural knowledge; and that is a true science, one that should be taught in all schools for the sake of its practical service to our country. . . .

Throughout the course the points here emphasised find abundant illustration, and often throw a curious light on the customs, the rural economy, the medicine, and the philosophy of the day. It would have been easy to pick out some delicious plums, but it seemed better to give, so far as might be in the words of Linnæus himself, the principles that guided him, and may still inspire us, in the illimitable study of nature.

F. A. B.

NOTES.

A GIFT of 20,000*l.* has been promised to London Hospital by Mrs. E. S. Paterson for cardiac research work.

ONCE again the Arctic claims its toll. The *Times* correspondent at Petrograd (St. Petersburg) reports that Lieut. Sedoff, the leader of a Russian attempt on the north pole, was taken ill at Hooker Island, Franz Josef Land, in September, 1913. The party was in dire straits in winter quarters, as the coal was all burnt and even parts of the ship were used for fuel. During February, 1914, a dash was made polewards; but, in March, Lieut. Sedoff, who had not recovered from his illness, died between Franz Josef Land and Rudolf Island. He had set out accompanied by two sailors and twenty-four dogs. The sailors buried the body, abandoned the dogs, and returned. The *Foka*, Sedoff's ship, had previously, in August, 1913, been useful in the rescue of two members of the Brousiloff Expedition. M. Brousiloff, with half the expedition, is reported still in his ship, the *St. Anna*, hoping that the current will carry the ship north of Spitsbergen, so that he can break through southwards. In consequence of the privations they had endured on the voyage from the Kara Sea, eleven members of the expedition left the ship; of these all perished but the two rescued by the *Foka*.

THE Board of Agriculture and Fisheries has received the following from the Agricultural Consultative Committee :—Milk-sellers or others who have a surplus of milk to dispose of are strongly urged to take steps to have it converted into cheese either in their own dairies or cooperatively. This method of dealing with surplus milk beyond what is required for immediate consumption will not only be found more remunerative than separating the milk and making the cream into butter, but will also be a useful means of contributing to the conservation of the food supply of the nation. The types of cheeses most suitable for manufacture in the circumstances are Cheddar, Cheshire, Derby, Leicester, and Gloucester, or such other varieties as do not deteriorate under reasonably prolonged storage.

IN the medical papers and in the *Times* the value of, and necessity for, anti-typhoid vaccination for all branches of the Army have been urged by Sir William Osler, Sir Lauder Brunton, and Sir William Leishman. Figures quoted by Sir William Leishman are eloquent as to the efficiency of the vaccination for the prevention of typhoid fever: in India, where formerly this disease among the British garrison cost us from 300–600 deaths annually, was last year responsible for fewer than twenty deaths, 93 per cent. of the men now being inoculated. Large supplies of the vaccine have been prepared at the Royal Army Medical College, while the department for therapeutic inoculation, St. Mary's Hospital, Paddington, has furnished nearly

280,000 doses of the vaccine for the use of the Army. Sir Almroth Wright, the author of anti-typhoid inoculation, points out in the *Times* that it is already compulsory in the French and American Armies, and he urges that it should now be made so also in the British Army. He states also that 180,000 doses of an "anti-sepsis" vaccine have been supplied to our Army and Navy, and also to the French military hospitals during the past three weeks. It is believed that this vaccine will be of great value in protecting our Army from bacterial infection of wounds.

A SUMMARY of the weather for the past summer as comprised in the thirteen weeks ending August 29 has been given by the Meteorological Office for all districts of the United Kingdom. The mean temperature for the summer is above the average in all parts of the British Isles. The excess is greatest in the north of Scotland and in the north and north-east of England, where it amounts to about 1·5°, and in the east and west of Scotland, the midland counties, and the north-west of England the excess is 1°. In the Channel Islands the excess of temperature is very trifling. The south-east of England is the only district in which the highest temperature has reached 90°. The aggregate rainfall for the summer varies considerably in different districts of the United Kingdom. The highest excess of the summer fall is 125 per cent. of the average in the south-west of England, in the north-east of England, and in the midland counties the fall is 112 per cent. of the average, and the Channel Islands is the only other district with an excess, with 107 per cent. of the average. In the north of Scotland the rainfall is only 71 per cent. of the average, and 78 per cent. in the west of Scotland and in the east of England. In the south-east of England the summer fall is 88 per cent. of the average. The duration of bright sunshine is generally in excess of the average.

PROF. O. SCHLAGINHAUFEN reviews the pygmy question in New Guinea in the *Festschrift der Dozenten der Universität Zürich*, 1914, and in Melanesia in the *Arch. Suisses d'Anthrop., Geneva*. 1914. He comes to the conclusion that in Melanesia we know of only one group which can be called pure pygmy, the Tapiro of West Netherlands, New Guinea, with a mean stature of 144·9 cm., described by Wollaston and Rawling. Then come four tribes, the Kamaweka of the Mekeo district, British New Guinea, noted by Seligmann, the Goliath group of Netherlands New Guinea, described by van den Broek, the Torricelli group, and Kai of German New Guinea, described by himself and Pöch respectively, all with a mean somewhere about 150 cm. These are often regarded as a mixture between true pygmies and tall varieties, but there is no proof of this. These five tribes inhabit the hilly interior. For all groups studied in New Guinea the general rule holds good that stature increases from inland to the coast, and the cephalic index (with some exceptions) decreases. The author holds that this association points to these being less racial characters than functions of geographical control. Dolichocephalism combined with low stature has not yet been observed in New Guinea or the Bismarck Archipelago. No distinct group of pygmies have been found as yet in the Bismarck Archipelago or the Solomon Islands, though very short people occur sporadically. The author gives an interesting coloured map showing the distributions of stature in New Guinea and the Bismarck Archipelago.

AN illustrated account of a sixteenth-century building at West Hoathly, Sussex, known as the Priest House, which has been restored and fitted up as a museum by Mr. Godwin King, appears in the *Museums Journal* for September. Admirable as is the restoration, it would have been better if the interior had been refitted according to the original plan. This, it is suggested, may, however, be indicated in a miniature model of the building.

IN his presidential address at the annual meeting of the new Zealand Institute (Proc., vol. xlvi.), Dr. C. Chilton paid a well-deserved tribute to the services rendered by the late Augustus Hamilton to that body, and also to the Dominion Museum, of which he was director. In a later part of the address the president directed attention to the unsatisfactory housing of the valuable specimens and the library of the Institute in the Dominion Museum. The majority of the specimens in portions of the collection—especially the examples of Maori workmanship and art—are irreplaceable, "yet they are still housed in a wooden building that is almost falling to pieces through age, and the greater part of which has been declared to be insanitary for human beings."

IN vol. iii., part 3, of Records of the W. Australian Museum, Mr. L. Glauert gives an account of new discoveries of mammalian remains in the so-called mammoth cave. The most interesting of these pertain to a big echidna, believed to have been double the size of the living Australian *Echidna aculeata*, and also exceeding in size any of the previously described extinct forms, one of which has been referred to the genus Zaglossus, or Proechidna, now confined to New Guinea. The new specimens are, however, considered to represent a still larger species, for which the name *Zaglossus hacketti* is proposed. In recording remains of the Tasmanian wolf and Tasmanian devil from the same cavern, Mr. Glauert incidentally mentions that an apparently wild individual of the latter species was killed near Melbourne in 1912.

IN an admirably thought-out article on the osteology of Permian reptiles, in No. 8 of vol. i. of Contributions from Walker Museum, published in this country by the Cambridge University Press, as agents for the University of Chicago Press, Mr. S. W. Williston gives certain very cogent reasons for deposing the New Zealand tuatera (Sphenodon) from its hitherto undisputed position as one of the most primitive reptiles with which we are acquainted. As the result of an elaborate study of the skeleton of the lizard-like Aræoscelis from the Permian of Texas, the author has come to the conclusion that in the earliest reptiles it is much more probable that the bony skull-roof inherited from the stegocephalian amphibians should have been perforated only once, rather than twice, on each side, and consequently that the two bony temporal arcades of the tuatera represent a more

specialised type than does the single one of lizards. And when once the matter is put before us in this straightforward manner, we can scarcely refrain from wondering why we never thought of it before. Aræoscelis, in which there is certainly but a single arcade, is regarded by the author as the typical representative of a group—Aræoscelidia—which shall include the European Permian genera, Protorosaurus and Kadaliosaurus, and the position of which should be next the Squamata (lizards and snakes). Ichthyosaurs, which never possessed a lower temporal vacuity, and are evidently a primitive group, are not improbably more or less nearly related to the Aræoscelida. Palæohatteria, on the other hand, which has long been associated with the European representatives of the last-named group, is in every essential character near akin to the Pelycosauria, in which it should typify a special family.

MR. JAMES RITCHIE, of the Royal Scottish Museum, has published a short but interesting paper on the fauna of a deep coal-pit in Midlothian. None of the animals show any indication of bleaching or blindness, and it is evident that all must have been artificially introduced, to a great extent, with the timber used as props. The only springtail in the list is *Tomocerus minor,* a species that happens to be constantly found in caves, but none of the characteristic white, blind cave-insects of the order Collembola were discovered in the coal-pit.

THE valuable series of "L.M.B.C. Memoirs" published by the Liverpool Marine Biology Committee has reached No. xxii., in which Mr. Herbert C. Chadwick, of the Port Erin station, describes the Echinoderm larvæ taken by tow-netting in the neighbouring waters. Most of the larvæ described are ophiuroid or echinoid plutei, the young stages of asteroids and holothuroids being unexpectedly scarce. The memoir is illustrated with nine plates of excellent structural figures.

DR. G. K. GILBERT, with the aid of Mr. E. C. Murphy, has made a characteristically thoughtful study of "The Transportation of Débris by Running Water" (U.S. Geol. Survey, Professional Paper 86, 1914). Working with an experimental trough some 30 ft. in length, which could be adjusted at various slopes, and another trough, 150 ft. in length, which was kept horizontal, measurements were made of the quantity of material of known grade carried forward by traction on a bed built up of similar grains and moulded by the flow. Such a bed represents the conditions that occur in nature, and "the material of the load is derived from and returned to the bed," in contrast with movement in "flume transportation," where the artificial channel has a rigid floor. "Saltation," where a particle is caught in an ascending swirl and shot forward for a time freely above the bed, plays an important part in transportation; and a particle "in suspension" may be regarded as making a very long leap of this kind. The present work, which does full justice to the complex phenomena, is concerned with traction and not with suspension.

DETAILS of severe shocks in the earthquake belt extending from Sumatra to New Guinea and the Carolines are published (in Japanese) in the Journal of the Meteorological Society of Japan for July, 1914. Two such earthquakes have occurred so far this year, details of which were recorded at the Osaka Seismological Observatory as follows:—(1) April 12, at 1h. 39m. 41s. a.m.; preliminary tremor lasting 7m. 22s., principal shock, 6m. 0s.; maximum amplitude, E.–W. movement at 1h. 57m. 5s., 632 microns, period 20·2s.; S.–N. movement at 1h. 58m. 1s., 747 microns, period 21·6s.; total duration of shock, E.–W. 2h. 11m., S.–N. 2h. 14m.; located near Gilbert Island, east of New Guinea. (2) May 26, at 11h. 29m. 56s. p.m.; preliminary tremor lasting 5m. 53s., principal shock, 3m. 4s.; maximum amplitude, E.–W. movement at 11h. 47m. 8s., 2187 microns, period 23·0s.; S.–N. movement at 11h. 50m. 41s., 4305 microns, period 20·8s.; total duration of shock, E.–W., 3h. 29m., S.–N., 3h. 33m.; located near Celebes. Nine earthquakes of a similar or greater magnitude than the latter, it is noted, have occurred in the same region since 1907, the intervals separating them showing a gradual diminution in length.

IN the last report of the Meteorological Committee mention was made of the increase in the sale of the *Daily Weather Report,* which is due largely to subscriptions from schools; for some years past back copies have been supplied for educational purposes at the cost of postage. A notable case of the use that may be made of these charts and other Meteorological Office publications is explained by Mr. W. E. Whitehouse, assistant lecturer in physical geography at Aberystwyth University College, in a pamphlet entitled "Suggestions for a Course in Climatology in Correlation with Geography," by means of which "a vital section" of the latter can be more systematically treated. The large number of questions for pupils cover most of the ground included under modern meteorology, and a student who could satisfactorily reply to the majority of them might claim to be well equipped in meteorological science. A useful bibliography has also been prepared in graded sections for the use of teachers and others. The pamphlet is prefaced by a very interesting introduction by Dr. Shaw; while fully recognising the practical and educational utility of the suggestions, he thinks (as we do) that the author is "very liberal in his interpretation of the scope of the science of climatology."

IN connection with the Canadian National Exhibition which has been opened at Toronto, the Imperial Department of Agriculture for the West Indies has issued an illustrated handbook under the title, "The West Indies in Canada," showing the main features of the industrial and trade relations of the West Indies, the nature of recent agricultural developments, and a description of the principal products of the islands. From this handbook it appears that Citrus planting is being rapidly extended in British Guiana and St. Lucia, tea is being planted in Jamaica, and cigars are now exported from Jamaica in considerable quantity. An interesting minor product is papaw, a

pleasant table fruit derived from *Carica papaya*, which is grown in Montserrat, and serves as a source of papain, a digestive ferment the demand for which is rapidly growing, especially in Canada, and the United States. The cultivation of rice is also being greatly developed in Trinidad and British Guiana.

IN the April number of the *Astrophysical Journal* Dr. Wali-Mohammad, of Aligarh College, India, described the results of his investigation of the degree of complexity of the spectral lines of aluminium, bismuth, cadmium, chromium, cobalt, copper, lead, magnesium, manganese, silver, sodium, tin and tellurium. As source of light he used a Wehnelt tube in which the kathode consisted of a platinum foil covered with oxides of barium and calcium, and the anode of the metal to be investigated contained in a porcelain tube. A potential difference of 200 volts was maintained between the anode and the red hot kathode. The tube was water-cooled and the pressure within it less than 0·01 mm. of mercury. The light passed out of the tube through a glass window at the top and was received by a Hilger echelon grating of 35 plates. The spectra were photographed on a series of plates each suitable for a part of the spectrum. The author found that few of the metals possessed complex lines, and of those that did copper, lead, and manganese had lines of similar structure. In nearly all cases the structure shown by the echelon agreed with that found previously by crossed Lummer plates.

IN the domain of electro-chemistry the greatest commercial developments recently have been in the utilisation of nitrogen from the atmosphere for the manufacture of nitrogen products. It is only since electrical power has been obtainable in large amount at exceptionally low cost that the operations have been carried out profitably on a commercial basis. Probably the most interesting of the processes for the fixation of atmospheric nitrogen is that in which calcium carbide is employed as the medium for the production of calcium cyanamide. We learn from *Engineering* for August 28 that the Odda works in Norway are now producing 85,000 tons of calcium carbide and 80,000 tons of calcium cyanamide per annum, a result due largely to the admirable mechanical appliances in use. The electric power available at Odda will soon be increased to 125,000 horse-power, and the carbide and cyanamide factories will be further enlarged. The Nitrogen Products and Carbide Company have acquired water-fall rights in Norway and Iceland which will enable a total of about one million horse-power to be generated—sufficient for the production of nearly two million tons of cyanamide per annum. It may be noted that the use of cyanamide as a fertiliser is increasing rapidly.

THE Carnegie Institution of Washington has published the second volume of the "Guide to the Materials for American History, to 1783, in the Public Record Office of Great Britain." This part contains departmental and miscellaneous papers, and is by Prof. C. M. Andrews, Farnam professor of American history in Yale University. The scope of the work and the method of treatment were explained when attention was directed to the publication of the first volume. The new part runs to 427 pages, and deals with papers of the Admiralty, the Lord Chamberlain, Custom House, Treasury, War Office, High Court of Admiralty, and other departments.

OUR ASTRONOMICAL COLUMN.

COMET 1913*f* (DELAVAN).—The following short ephemeris gives the positions of Delavan's comet (1913*f*) for the current month:—

Greenwich Midnight.

		R. A. h. m. s.		Dec. ° ′
September 8	...	9 8 35	...	+49 56
16	...	10 8 6	...	49 51
24	...	11 9 33	...	47 56

The comet is now in the constellation of Ursa Major, and is not far from the two third magnitude stars κ and ι. On clear nights it is a conspicuous object in the northern heavens, and is easily picked up from the rough chart given in this column for last week. It is gradually becoming brighter, but the occurrence of bright moonlight during the last week has made observations somewhat difficult.

THE RECENT ECLIPSE EXPEDITIONS.—Further news is to hand regarding some of the observers who went out to observe the total eclipse of the sun. The *Morning Post* of September 3 gives some information about the party from the Royal Observatory, Greenwich, through Mr. Hepburn. Mr. Hepburn accompanied this party as a volunteer assistant to Minsk, in Russia, and they observed the eclipse under satisfactory conditions. He left there on the Sunday after the eclipse, but while most of the plates exposed were then not developed, one that was developed showed the spectrum of the chromosphere. Mr. Hepburn arrived in England on September 1 *viâ* Finland, Norway, and the North Sea, and he expected the official members of the party to be home on about September 6. It is stated that the instruments will be sent to the Russian Imperial Observatory at Pulkovo, where Prof. Backlund, the director, has arranged to keep them pending a favourable opportunity to return them to Greenwich. Mr. R. C. Slater had arranged to go to Riga (Russia) to make his observations, and sent his instruments there direct. He found, according to the *Times* of August 31, that he was unable to cross the Baltic. Having with him only a 4-in. lens he rigged up a camera and made his observations at Strömsum, in Sweden. With this he was successful, and he is recorded to have brought back with him excellent photographs of the corona.

THE MIRRORS OF THE HELWAN KHEDIVIAL OBSERVATORY.—Bulletin No. 12 of the Khedivial Observatory at Helwan is devoted to accounts of the photographic tests of the figures of the new and old thirty-inch mirrors by Messrs. Walter S. Adams and H. Knox-Shaw respectively. The new mirror, the gift of Mr. Astor, was figured by Mr. Ritchey at Pasadena, and the method of testing was that of Hartmann. In the first tests a small amount of astigmatism was indicated in the zones along the 0° and 90° diameters, but none along the 45° and 135° diameters, or, in other words, the figure of revolution of the mirror was fairly good. A comparison of the computed and observed values of the focal lengths of the zones showed that the central zones were still greatly undercorrected. Further work in the mirror by Mr. Ritchey has greatly improved it, and a second series of tests has indicated that the agreement of the

observed with the theoretical figure is remarkably close; in fact Mr. Adams states that "the mirror may accordingly be regarded as essentially perfect to within the limit defined in this way." A similar set of tests made by Mr. Knox-Shaw on the old thirty-inch Common mirror *in situ* in the telescope. He found that the mirror was uncorrected by about twice as much as was the Ritchey mirror at the time of the first series of tests mentioned above. From tests of the astigmatism he concludes that the position of the telescope has an appreciable effect on the figure of the mirror as has been suspected to be the case.

PLANT-LIFE AT THE SNOW-LINE.[1]

MR. JOSIAS BRAUN'S exhaustive account of the vegetation at the snow-line in the south-eastern (Rhætian-Lepontine) Alps forms a valuable contribution to our knowledge of the plant-ecology of the Swiss Alps. The area includes, roughly speaking, the country from the St. Gothard to the Engadine. The text consists of two parts. The first is a consideration of the vegetation in relation to external conditions, with a detailed description of the plant-associations. The zone under consideration is defined as that in which the summer heat just suffices to melt the annual heavy snow-fall on level areas; its altitude ranges from 2960 metres on the Bernina chain to 2650 metres in the St. Gothard group. It lies above the region of close turf, and forms a part of the open rock region. Within it the author distinguishes three secondary zones: (1) the "Pionierrasengurtel," the isolated outposts, so to say, of the turf-flora, forming patches in wind-sheltered places or on sunny spots; (2) the "Dicotyledonous zone," characterised mainly by cushion-forming Dicotyledonous plants; and (3) the "Thallophyte-zone" of rock-inhabiting lichens. The principal natural formations in the first zone are the Curvuletum, of which *Carex curvula* is a characteristic component, and the Elynetum, in which *Elyna myosuroides* predominates. Here, too, are found the last traces of the influence of man and his domesticated animals, indicated by luxuriance of *Poa alpina*. The last chapter of the first part deals with the fauna of the area, which comprises ninety-one species, mainly insects and spiders.

The second part comprises a systematic account of the flora. This includes two ferns, *Cystopteris fragilis* and *Asplenium viride, Botrychium lunaria, Lycopodium selago, Juniperus communis* var. *montana*, and 219 angiospermous flowering plants. The latter represent twenty-nine families, those most in evidence being, in order of numerical preponderance., Compositæ, Gramineæ, Caryophyllaceæ, Saxifragaceæ, Cruciferæ, Rosaceæ, Leguminosæ, Gentianaceæ, and Primulaceæ, which together contain two-thirds of the whole flora. The proportion of Monocotyledons to Dicotyledons is slightly less than at lower levels, namely, 1 : 4·3 as compared with 1 : 3·6. There are nine woody plants: Juniper, three Willows, *Empetrum nigrum, Loiseleuria* (*Azalea*) *procumbens*, and three species of Vaccinium. The best represented genera are Saxifraga, sixteen species; Gentiana, ten species; Carex, nine species; Festuca, Draba, and Cerastium, each with six species; and Alchemilla and Primula each with five. A comparison with the Arctic flora of the west coast of Greenland, between N. lat. 69° and 71°, which contains approximately the same number of flowering plants, shows considerable agreement between the two. There is, however, a much greater proportion of marsh plants in the Arctic flora, while in the Alpine the families Compositæ, Primulaceæ, Gentianaceæ, and Leguminosæ are more richly represented.

The author groups the snow-flora of this district of the Alps under five main headings: (1) an endemic-Alpine element, peculiar to the Alps, comprising twenty-nine species (13 per cent.); (2) a European-Alpine element with ninety-five species (42·4 per cent.); (3) a Eurasiatic element with fourteen species (6·2 per cent.), which occur also in Central Asia, but do not reach the polar circle; (4) an Arctic-Alpine element with seventy-one species (31·7 per cent.); (5) a ubiquitous element, fifteen species (6·7 per cent.), of more widely distributed plants in lower levels.

[1] Nouveaux Mémoires de la Société Helvétique des Sciences Naturelles, vol. xviii. Pp. vii+347+map+4 plates.

RECENT WORK ON ENTOMOLOGY.

THE American representatives of the minute homopterous insects commonly known as jumping plant-lice (Psylliidæ) form the subject of an elaborate memoir by Mr. D. L. Crawford, published as Bulletin No. 85 (168 pp.) of the U.S. National Museum. These widely-spread insects frequent trees and shrubs, where, from their active habits, they are difficult to capture without the aid of a net. When disturbed, they throw themselves into the air by means of their powerful hind-legs, and when once launched, are able to propel themselves some considerable distance by rapidly vibrating the wings, although they are not endowed with the power of prolonged flight.

Mr. Crawford found the current classification of the group—largely based on wing-venation—to be altogether untrustworthy, closely related species being in many instances placed in different genera. A more satisfactory basis for classification is afforded by the structure of the head; and from this and other features the author proposes a new taxonomic scheme, with the description of many new species.

Cicalas and other Homoptera collected during the second expedition of the Duke Adolf Friedrich of Mecklenburg are described by Dr. L. Melichar in Lief. 5 of Band i. of *Ergebnisse der Zweiten Deutschen Zentral-Afrika-Expedition*, 1910–11. The collection included 184 specimens, referable to 65 species, of which 18 appeared to be new, some of these likewise representing three new genera types.

In the first article of Lief. 4 of the publication just quoted, Prof. Y. Sjöstedt records the white ants observed and obtained during the expedition. Special interest attaches to photographs of the interior of a nest of *Termites natalensis*, showing, not only a "fungus-garden," but also the royal cells, of which one contains the monstrous, overgrown queen, and a second, in close proximity, the diminutive king.

In connection with the above may be noticed the description, by Mr. S. Hozawa, in *Annot. Zool. Japon*, vol. viii., parts 3 and 4, of a new species of termite-eating beetle from Formosa. It belongs to the tenebrionid genus, Zielas, previously known only by a single species from Annam, of which the habits have not been observed, although, from its affinity to termitophilous genera, it has been assumed to feed on white ants. The elongated eyes, degenerate hind-wings, and sluggish movements of the Formosan species are doubtless connected with its mode of life.

Three issues of the Journal of the College of Agriculture, Tohoku Imperial University, Sapporo, Japan, are to hand, two of which (vol. v., parts 6 and 7) are devoted to various groups of Japanese insects, with descriptions of a number of new species and genera, while the third (vol. vi., part 1) contains further observations on reduplication in silkworms.

Pine timber in a district in Montana, between the Swan and Clearwater rivers, is seriously menaced by

the larvæ of the sequoia pitch-moth (*Vespamima sequoiae*). According to a leaflet by Mr. J. Brunner, issued as Bulletin No. 111 of the U.S. Department of Agriculture, it specially attacks the so-called lodge-pole pine, in which it propagates; other trees in the vicinity of those attacked are endangered by the forest-fires fed by the timber killed by the larvæ. Destruction of the larvæ themselves seems the only efficient preventive of the infestation.

Experiments recently undertaken in the United States, as recorded by Mr. B. R. Cond, in vol. ii., No. 3, of the *Journal of Agricultural Research,* have shown that the larvæ of the boll-weevil (*Anthorromus gravelis*) can and do feed on plants other than cotton, as, for example, on *Hibiscus syriacus*.

The Board of Agriculture has issued a leaflet (No. 286) on the two species of narcissus-flies, *Merodon equestris* and *Eumerus strigatus,* the grubs of which attack the bulbs of daffodils and other narcissi. The first and larger species, which was, at one time, supposed to have been introduced from the continent into this country, where it has been recognised since 1869, but in the opinion of at least one economic entomologist is probably indigenous, although it only became abundant with the development of daffodil-culture. The second and smaller species is a recent introduction, but, from its destructive nature, is likely to become as serious a pest as the first. The life-history of each species is described, with suggestions for remedial measures.

The July and August numbers of the *Entomologist's Monthly Magazine* contain two instalments of an account, by Mr. J. J. Walker, R.N., of the spread of the American butterfly *Danaida plexippus* to the islands of the south Pacific and Australia. Following one of its food-plants—a milk-weed of the genus Asclepias—it appears to have reached Hawaii between 1845 and 1850, whence a gravid female (or possibly a pair) was probably carried to Ponape, in the Caroline group. From this solitary individual (or pair) have probably sprung the swarms now spread over the South Sea islands, in many of which this species is the commonest of all butterflies.

The most important item in Prof. G. H. Carpenter's report on injurious insects in Ireland during 1913 (Economic Proc., R. Dublin Soc., vol. ii., No. 9), relates to the damage caused by the frit-fly (*Oscinis frit*) to corn crops. This little black fly is a recent introduction to Ireland, and in May and June of last year its maggots were very destructive to a field of oats in Tyrone. Its early life-history is detailed in an article by Mr. T. R. Hewitt in vol. xiv., No. 23, of the Scientific Proceedings of the Royal Dublin Society; and this account is incorporated in Prof. Carpenter's report. R. L.

THE AUSTRALIAN MEETING OF THE BRITISH ASSOCIATION.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY SIR CHARLES P. LUCAS, K.C.B., K.C.M.G., PRESIDENT OF THE SECTION.

Man as a Geographical Agency.

In an inaugural address to the Royal Scottish Geographical Society on geography and statecraft Lord Milner said: "If I have no right to call myself a geographer, I am at least a firm believer in the value of geographical studies." I wish to echo these words. I have no expert geographical knowledge, and am wholly unversed in science, but I am emboldened to try to say a few words because of my profound belief in the value of geographical studies. I believe in their value partly on general grounds, and largely because a study of the British Empire leads an Englishman, whether born in England or in Australia, to the inevitable conclusion that statecraft in the past would have been better, if there had been more accurate knowledge of geography. This statement might be illustrated by various anecdotes, some true, not a few apocryphal; but anecdotes do not lend themselves to the advancement of science. I am encouraged, too, to speak because the field of geography is more open to the man in the street than are the sciences more strictly so-called. It is a *graphy*, not a *logy*. Geology is the science of the earth. Geography is a description of the face of the earth and of what is on or under it, a series of pictures with appropriate letterpress and with more or less appropriate morals to adorn the tale. The man in the street may talk affably and even intelligently about the face of the earth.

Taking the earth as it is, geographical discovery has well-nigh reached its limit. The truth, in the words of Addison's hymn, is now "spread from Pole to Pole," and recent exploration at the South Pole, with its tale of heroism, will have specially appealed to the citizens of this Southern land. Coasts are in most cases accurately known. The age of Cook and Flinders is past. Interiors are more or less known. In Africa there is no more room for Livingstones, Spekes, Burtons, and Stanleys. In Australia Sir John Forrest is an honoured survival of the exploring age—the age of McDouall Stuart and other heroes of Australian discovery. The old map-makers, in Swift's well-known lines, "o'er unhabitable downs placed elephants for want of towns." Towns have now taken the place of elephants and of kangaroos. Much, no doubt, still remains to be done. The known will be made far better known; maps will be rectified; many great inland tracts in Australia and elsewhere will be, as they are now being, scientifically surveyed; corners of the earth only penetrated now will be swept and garnished. But as we stand to-day, broadly speaking, there are few more lands and seas to conquer. Discovery pure and simple is passing away.

But meanwhile there is one side of geography which is coming more and more to the front, bringing it more than ever within the scope of the British Association for the Advancement of Science. "Man is the ultimate term in the geographical problem," said Dr. Scott Keltie some years since at the meeting at Toronto. "Geography is a description of the earth as it is, in relation to man," said Sir Clements Markham, long president of the Royal Geographical Society. Geography, I venture to think, is becoming more and more a description of the earth as it is and as it will be under the working hand of man. It is becoming intensive rather than extensive. Geographers have to record, and will more and more have to record, how far man has changed and is changing the face of the earth, to try to predict how far he will change it in the coming centuries. The face of the earth has been unveiled by man. Will the earth save her face in the years before us, and, if she saves her face, will it be taken at face value? How far, for instance, will lines of latitude and longitude continue to have any practical meaning?

Man includes the ordinary man, the settler, the agriculturist; man includes, too, the extraordinary—the man of science, the inventor, the engineer. "Man," says a writer on the subject, "is truly a geographical agency," and I ask you to take account of this agency for a few minutes. I do so more especially because one of the chief features of the present day is the rise

of the South; and the rise of the South—notably of Australia—is the direct result of human agency, on one hand transforming the surface of the land, on the other eliminating distance. The old name of Australia, as we all know, was New Holland. The name was well chosen in view of later history, for while no two parts of the world could be more unlike one another than the little corner of Europe known as Holland, or the Netherlands, and the great Southern Continent, in one and in the other man has been pre-eminently a geographical agency.

The writer who used this phrase, "Man is a geographical agency," the American writer, Mr. G. P. Marsh, published his book, "Man and Nature," in 1864, and a new edition, entitled "The Earth as Modified by Human Action," in 1874. He was mainly concerned with the destructiveness of man in the geographical and climatic changes which he has effected. "Every plant, every animal," he writes, "is a geographical agency, man a destructive, vegetables, and in some cases even wild beasts, restorative powers"; and again: "It is in general true that the intervention of man has hitherto seemed to ensure the final exhaustion, ruin, and desolation of every province of Nature which he has reduced to his dominion." The more civilised man has become, he tells us, the more he has destroyed. "Purely untutored humanity interferes comparatively little with the arrangements of Nature, and the destructive agency of man becomes more and more energetic and unsparing as he advances in civilisation." In short, in his opinion, "better fifty years of Cathay than a cycle of Europe."

He took this gloomy view mainly on account of the mischief done by cutting down forests. Man has wrought this destruction not only with his own hand, but through domesticated animals more destructive than wild beasts, sheep, goats, horned cattle, stunting or killing the young shoots of trees. Writing of Tunisia, Mr. Perkins, the Principal of Roseworthy College, says: "In so far as young trees and shrubs are concerned, the passage of a flock of goats will do quite as much damage as a bush fire." Mr. Marsh seems to have met a fool in the forest, and it was man; and he found him to be more knave than fool, for man has been, in Mr. Marsh's view, the revolutionary Radical confiscating Nature's vested interests. "Man," he says, "has too long forgotten that the earth was given to him for usufruct alone, not for consumption, still less for profligate waste." Trees, to his mind, are Conservatives of the best kind. They stand in the way, it is true, but they stop excesses, they moderate the climate, they give shelter against the wind, they store the water, prevent inundations, preserve and enrich the soil. "The clearing of the woods," he says, "has in some cases produced within two or three generations effects as blasting as those generally ascribed to geological convulsions, and has laid waste the face of the earth more hopelessly than if it had been buried by a current of lava or a shower of volcanic sand"; and, once more, where forests have been destroyed, he says, "The face of the earth is no longer a sponge but a dust-heap."

The damage done by cutting down trees, and thereby letting loose torrents which wash away the soil, is or was very marked in the south of France, in Dauphiné, Provence, and the French Alps. With the felling of trees and the pasturing of sheep on the upper edge of the forest—for sheep break the soil and expose the roots—the higher ground has been laid bare. Rainstorms have in consequence swept off the soil, and the floods have devastated the valleys. The mountainsides have become deserts, and the valleys have been turned into swamps. "When they destroyed the forest," wrote the great French geographer, Reclus, about thirty years ago, "they also destroyed the very ground on which it stood"; and then he continues: "The devastating action of the streams in the French Alps is a very curious phenomenon from the historical point of view, for it explains why so many of the districts of Syria, Greece, Asia Minor, Africa, and Spain have been forsaken by their inhabitants. The men have disappeared along with the trees; the axe of the woodman, no less than the sword of the conqueror, has put an end to, or transplanted, entire populations." In the latter part of the South African war Sir William Willcocks, skilled in irrigation in Egypt, and now reclaiming Mesopotamia, was brought to South Africa to report upon the possibilities of irrigation there, and in his report dated November 1901 he wrote as follows: "Seeing in Basutoland the effect of about thirty years of cultivation and more or less intense habitation convinced me of the fact that another country with steep slopes and thin depth of soil, like Palestine, has been almost completely denuded by hundreds of years of cultivation and intense habits. The Palestine which Joshua conquered and which the children of Israel inhabited was in all probability covered over great part of its area by sufficient earth to provide food for a population a hundred times as dense as that which can be supported to-day." The Scotch geologist, Hugh Miller, again, attributed the formation of the Scotch mosses to the cutting down of timber by Roman soldiers. "What had been an overturned forest became in the course of years a deep morass."

In past times there have been voices raised in favour of the forests, but they have been voices crying in the desert which man has made. Here is one. The old chronicler Holinshed, who lived in the reign of Queen Elizabeth, noted the amount of timber cut down for house building and in order to increase the area for pasturage. "Every small occasion in my time," he writes, "is enough to cut down a great wood"; and in another passage either he himself or one of his collaborators writes that he would wish to live to see four things reformed in England: "The want of discipline in the Church, the covetous dealing of most of our merchants in the preferment of commodities of other countries and hindrance of their own, the holding of fairs and markets upon the Sunday to be abolished and referred to the Wednesdays, and that every man in whatever part of the champaine soil enjoyeth forty acres of land and upwards after that rate, either by free deed, copyhold or fee farm, might plant one acre of wood or sow the same with oke mast, hazell, beach, and sufficient provision be made that it be cherished and kept."

Mr. Marsh seems to have thought that the Old World, and especially the countries which formed the old Roman Empire, had been ruined almost past redemption; and for the beneficent action of man on Nature he looked across the seas. "Australia and New Zealand," he writes, "are perhaps the countries from which we have a right to expect the fullest elucidation of these difficult and disputable problems. Here exist greater facilities and stronger motives for the careful study of the topics in question than have ever been found combined in any other theatre of European colonisation."

His book was first written half a century ago. He was a pessimist evidently, and pessimists exaggerate even more than optimists, for there is nothing more exhilarating and consoling to ourselves than to predict the worst possible consequences from our neighbour's folly. Further, though it may be true that man became more destructive as he became more civilised, it is also true that the destruction has been wrought directly rather by the unscientific than by the man of

science. If we have not grown less destructive since, at any rate we have shown some signs of penitence, and science has come to our aid in the work of reparation. Governments and associations have directed their attention to protecting woodland and reafforesting tracts which have been laid bare. The Touring Club of France, for instance, I am told, have taken up the question of the damage done by destruction of trees by men and sheep in Haute Savoie, and they assist reclamation by guidance and by grants. In England, under the auspices of Birmingham University and under the Presidency of Sir Oliver Lodge, the Midlands Reafforestation Association is planting the pit mounds and ash quarries of the Black Country with trees which will resist smoke and bad air, alders, willows, poplars, carrying out their work, a report says, under a combination of difficulties not to be found in any other country. Artificial lakes and reservoirs again, such as I shall refer to presently, are being made woodland centres. In most civilised countries nowadays living creatures are to some extent protected, tree planting is encouraged by Arbour days, and reserves are formed for forests, for beasts and birds, the survivors of the wild fauna of the earth. Some lands, such as Greece, as I gather from Mr. Perkins' report, are still being denuded of trees, but as a general rule the human conscience is becoming more and more alive to the immorality and the impolicy of wasting the surface of the earth and what lives upon it, and is even beginning to take stock as to whether the minerals beneath the surface are inexhaustible. Therefore I ask you now to consider man as the lord of creation in the nobler sense of the phrase as transforming geography, but more as a creative than as a destructive agency.

How far has the agency of man altered, and how far is it likely to alter, the surface of the earth, the divisions and boundaries assigned by Nature, the climate, and the production of the different parts of the globe; and, further, how far, when not actually transforming Nature, is human agency giving Nature the go-by? It should be borne in mind that science has effected, and is effecting transformation, partly by applying to old processes far more powerful machinery, partly by introducing new processes altogether; and that, as each new force is brought to light, lands and peoples are to a greater or less extent transformed. The world was laid out afresh by coal and steam. A new readjustment is taking place with the development of water power and oil power. Lands with no coal, but with fine water power or access to oil, are asserting themselves. Oil fuel is prolonging continuous voyages and making coaling stations superfluous. But of necessity it is the earth itself which gives the machinery for altering its own surface. The application of the machinery is contributed by the wit of man.

The surface of the earth consists of land and water. How far has human agency converted water into land or land into water, and how far, without actually transforming land into water and water into land, is it for practical human purposes altering the meaning of land and water as the great geographical divisions? A writer on the Fens and South Lincolnshire has told us: "The Romans, not content with appropriating land all over the world, added to their territory at home by draining lakes and reclaiming marshes." We can instance another great race which, while appropriating land all over the world, has added to it by reclaiming land from water, fresh or salt. The traveller from Great Britain to the most distant of the great British possessions, New Zealand, will find on landing at Wellington a fine street, Lambton Quay, the foreshore of the old beach, seaward of which now rise many of the city's finest buildings on land reclaimed from the sea; and instances of the kind might be indefinitely multiplied. Now the amount of land taken from water by man has been taken more from fresh water than from sea, and, taken in all, the amount is infinitesimal as compared with the total area of land and water; but it has been very considerable in certain small areas of the earth's surface, and from these small areas have come races of men who have profoundly modified the geography and history of the world. This may be illustrated from the Netherlands and from Great Britain.

Motley, at the beginning of "The Dutch Republic," writes of the Netherlands: "A region, outcast of ocean and earth, wrested at last from both domains their richest treasures." Napoleon was credited with saying that the Netherlands were a deposit of the Rhine, and the rightful property of him who controlled the sources; and an old writer pronounced that Holland was the gift of the ocean and of the rivers Rhine and Meuse, as Egypt is of the river Nile. The crowning vision of Goethe's Faust is that of a free people on a free soil, won from the sea and kept for human habitation by the daily effort of man. Such has been the story of the Netherlands. The Netherlands, as a home for civilised men, were, and are, the result of reclamation, of dykes and polders. The kingdom has a constantly changing area of between 12,000 and 13,000 square miles. Mr. Marsh, in his book, set down the total amount gained to agriculture at the time he wrote "by dyking out the sea and by draining shallow bays and lakes" at some 1370 square miles, which, he says, was one-tenth of the kingdom; at the same time, he estimated that much more had been lost to the sea—something like 2600 square miles. He writes that there were no important sea dykes before the thirteenth century, and that draining inland lakes did not begin until the fifteenth, when windmills came into use for pumping. In the nineteenth century steam pumps took the place of windmills, science strengthening an already existing process. Between 1815 and 1855, 172 square miles were reclaimed, and this included the Lake of Haarlem, some thirteen miles long by six in breadth, with an area of about seventy-three square miles. This was reclaimed between 1840 and 1853. At the present time, we are told, about forty square miles are being reclaimed annually in Holland; and meanwhile the Dutch Government has in contemplation or in hand a great scheme for draining the Zuyder Zee, which amounts to recovering from the ocean land which was taken by it in historic times at the end of the fourteenth century. The scheme is to be carried out in thirty-three years and is to cost nearly sixteen million pounds. The reclamation is to be effected by an embankment across the mouth of this inland sea over eighteen miles long. The result will be to add 815 square miles of land to the kingdom of the Netherlands, 750 square miles of which will be fertile land, and in addition to create a much-needed freshwater lake with an area of 557 square miles; this lake is to be fed by one of the mouths of the Rhine.

London is partly built on marsh. The part of London where I live, Pimlico, was largely built on piles. A little way north, in the centre of fashion, is Belgrave Square, and here a lady whom I used to know had heard her grandfather say that he had shot snipe. Take the City of London in the strict and narrow sense. The names of Moorfields and Fensbury or Finsbury are familiar to those who know the City. Stow, in his Survey of London, more than three hundred years ago, wrote of "The Moorfield which lieth without the postern called Moorgate. This field of old time was called the Moor. This fen or moor

field, stretching from the wall of the city betwixt Bishopsgate and the postern called Cripplegate to Fensbury and to Holywell continued a waste and unprofitable ground a long time." By 1527, he tells us, it was drained "into the course of Walbrook, and so into the Thames, and by these degrees was this fen or moor at length made main and hard ground, which before, being overgrown with flags, sedges and rushes, served to no use." It is said that this fen or marsh had come into being since Roman times. The reclamation which has been carried out in the case of London is typical of what has been done in numerous other cases. As man has become more civilised, he has come down from his earlier home in the uplands, has drained the valley swamps, and on the firm land thus created has planted the streets and houses of great cities.

The Romans had a hand in the draining of Romney Marsh in Sussex, and here nature cooperated with man, just as she has cooperated in the deltas of the great rivers, for the present state of the old Cinque Ports, Rye and Winchelsea, shows how much on this section of the English coast the sea has receded. But the largest reclamation was in East Anglia, where the names of the Fens and the Isle of Ely testify to what the surface once was. "For some of our fens," writes Holinshed, "are well known to be either of ten, twelve, sixteen, twenty or thirty miles in length. . . . Wherein also Elie, the famous isle, standeth, which is seven miles every way, and whereunto there is no access but by three causies." Arthur Young, in 1799, in his "General View of the Agriculture of the County of Lincoln," a copy of which he dedicated to that great friend of Australia, Sir Joseph Banks, who was a Lincolnshire landowner and a keen supporter of reclamation, wrote of the draining which had been carried out in Lincolnshire. "The quantity of land thus added to the kingdom has been great; fens of water, mud, wild fowl, frogs and agues have been converted to rich pasture and arable worth from 20*s.* to 40*s.* an acre . . . without going back to very remote periods, there cannot have been less than 150,000 acres drained and improved on an average from 5*s.* an acre to 25*s.*" 150,000 acres is about 234 square miles, but the amount reclaimed by draining in Lincolnshire in the seventeenth, eighteenth and nineteenth centuries seems to have been more than 500 square miles. The Fenlands as a whole extended into six counties. They were seventy miles in length, from ten to thirty miles broad, and covered an area of from 800 to 1000 square miles. One estimate I have seen is as high as 1200 square miles. Mr. Prothero, in his book on "English Farming, Past and Present," tells us that they were "in the seventeenth century a wilderness of bogs, pools and reed shoals—a vast morass from which here and there emerged a few islands of solid earth." In the seventeenth century a Dutch engineer, Vermuyden, was called in to advise, and the result of draining what was called after the peer who contracted for it the Bedford Level, together with subsequent reclamations, was to convert into ploughland and pasture large tracts which, in the words of an old writer, Dugdale, had been "a vast and deep fen, affording little benefit to the realm other than fish or fowl, with overmuch harbour to a rude and almost barbarous sort of lazy and beggarly people." In Lincolnshire there was a district called Holland, and in Norfolk one called Marshland, said to have been drained by, to quote Dugdale again, "those active and industrious people, the Romans."

The Dutch and the English, who thus added to their home lands by reclamation, went far and wide through the world, changing its face as they went. The Dutch, where they planted themselves, planted trees also; and when they came to land like their own Netherlands, again they reclaimed and empoldered. The foreshore of British Guiana, with its canals and sea defences, dating from Dutch times, is now the chief sugar-producing area in the British West Indies. If again in Australia man has been a geographical agency, he learnt his trade when he was changing the face of his old home in the British Isles.

Instances of reclaiming land from water might be indefinitely multiplied. We might compare the work done by different nations. In Norway, for instance, Reclus wrote that "the agriculturists are now reclaiming every year forty square miles of the marshes and fiords." Miss Semple, who, in the "Influences of Geographic Environment," writes that "between the Elbe and Scheldt" (that is, including with the Netherlands some of North Germany) "more than 2000 square miles have been reclaimed from river and sea in the past 300 years," tells us also that "the most gigantic dyke system in the world is that of the Hoangho, by which a territory of the size of England is won from the water for cultivation." Or we might take the different objects which have impelled men here and there to dry up water and bank out sea. Agriculture has not been the only object, nor yet reclaiming for town sites. Thus, in order to work the hematite iron mines at Hodbarrow, in Cumberland, an area of 170 acres was, in the years 1900–04, reclaimed from the sea by a barrier more than $1\frac{1}{4}$ miles long, designed by the great firm of marine engineers, Coode and Matthews, which built the Colombo breakwater. The reclaimed land, owing to the subsidence caused by the workings, is now much below the level of the sea. Here is an instance of reclamation not adding to agricultural or pastoral area, but giving mineral wealth, thereby attracting population and enriching a district.

How far has land been drowned by the agency of man? Again the total area is a negligible quantity, but again, relatively to small areas, it has been appreciable, and the indirect effects have been great. The necessities of town life are responsible for new lakes and rivers. Such are the great reservoirs and aqueducts by which water is being brought to New York from the Catskill Mountains, a work which a writer in the *Times* has described as "hardly second in magnitude and importance to the Panama Canal." In Great Britain cities in search of a water supply have ordered houses, churches, fields to be drowned, and small lakes to come into existence. Liverpool created Lake Vyrnwy in Montgomeryshire, with a length of nearly five miles and an area of 1121 acres. Birmingham is the parent of a similar lake in a wild Radnorshire valley near my old home. The water is not carried for anything like the distance from Mundaring to Kalgoorlie, and on a much greater scale than these little lakes in Wales is the reservoir now being formed in New South Wales by the Burrinjuck dam, on the Murrumbidgee River, which, as I read, is, or will be, forty-one miles long, and cover an area of twenty square miles. If I understand right, in this case, by holding up the waters of a river, a long narrow lake has been or is being called into existence. A still larger volume of water is gathered by the great Assouan dam, which holds up the Nile at the head of the First Cataract, washing, and at times submerging, the old temples on the Island of Philæ in mid-stream. First completed in 1902, the dam was enlarged and heightened by 1912; and the result of the dam is at the time of high Nile to create a lake of some 65 square miles in area, as well as to fill up the channel of the river for many miles up stream. Illustrations of artificial lakes might be multiplied from irrigation works in India. An official report on the State of Hyderabad, written some years ago, has the following reference to the tanks in the granitic country of that State: "There are no natural lakes, but from the

earliest times advantage has been taken of the undulating character of the country to dam up some low ground or gorge between two hills, above which the drainage of a large area is collected. Such artificial reservoirs are peculiar to the granitic country, and wherever groups of granite hills occur tanks are sure to be found associated with them." Take again the great ship canals. The Suez Canal runs for 100 miles from sea to sea, though for part of its course it runs through water, not through sand. It is constantly growing in depth and width. Its original depth was 26½ ft.; it is now, for nine-tenths of its length, more than 36 ft., and the canal is to be further deepened generally to more than 39 ft. Its original width at the bottom was 72 ft.; it is now, for most of its course, more than 147 ft.; in other words, the width has been more than doubled. A writer in the *Times* on the wonderful Panama Canal said: "The locks and the Gatun dam have entailed a far larger displacement of the earth's surface than has ever been attempted by the hand of man in so limited a space." Outside the locks the depth is 45 ft., and the minimum bottom width 300 ft. The official handbook of the Panama Canal says: "It is a lake canal as well as a lock canal, its dominating feature being Gatun Lake, a great body of water covering about 164 square miles." The canal is only fifty miles long from open sea to open sea, from shore line to shore line only forty. But in making it man, the geographical agency, has blocked the waters of a river, the Chagres, by building up a ridge which connects the two lines of hills between which the river flows, this ridge being a dam 1½ miles long, nearly half a mile wide at its base, and rising to 105 ft. above sea-level, with the result that a lake has come into existence which is three-quarters of the size of the Lake of Geneva, and extends beyond the limits of the Canal zone.

Mr. Marsh, in his book, referred to far more colossal schemes for turning land into water, such as flooding the African Sahara or cutting a canal from the Mediterranean to the Jordan and this submerging the basin of the Dead Sea, which is below the level of the ocean. The effect of the latter scheme, he estimated, would be to add from 2000 to 3000 square miles to the fluid surface of Syria. All that can be said is that the wildcat schemes of one century often become the domesticated possibilities of the next and the accomplished facts of the third; that the more discovery of new lands passes out of sight the more men's energies and imagination will be concentrated upon developing and altering what is in their keeping; and that, judging from the past, no unscientific man can safely set any limit whatever to the future achievements of science.

But now, given that the proportion of land to water and water to land has not been, and assuming that it will not be, appreciably altered, has water, for practical purposes, encroached on land, or land on water? In many cases water transport has encroached on land transport. The great isthmus canals are an obvious instance; so are the great Canadian canals. The tonnage passing through the locks of the Sault St.-Marie is greater than that which is carried through the Suez Canal. Waterways are made where there was dry land, and more often existing inland waterways are converted into sea-going ways. Manchester has become a seaport through its Ship Canal. The Clyde, in Mr. Vernon Harcourt's words, written in 1895, has been "converted from an insignificant stream into a deep navigable river capable of giving access to ocean-going vessels of large draught up to Glasgow." In 1758 the Clyde at low water at Glasgow was only 15 inches deep, and until 1818 no seagoing vessels came up to Glasgow. In 1895 the depth at low water was from 17 to 20 ft., and steamers with a maximum draught of 25½ ft. could go up to Glasgow. This was the result of dredging, deepening and widening the river, and increasing the tidal flow. The record of the Tyne has been similar. The effect of dredging the Tyne was that in 1895—I quote Mr. Harcourt again—"Between Shields and Newcastle, where formerly steamers of only 3 to 4 ft. draught used to ground for hours, there is now a depth of 20 ft. throughout at the lowest tides." It is because engineers have artificially improved Nature's work on the Clyde and the Tyne that these rivers have become homes of shipbuilding for the whole world. Building training walls on the Seine placed Rouen, seventy-eight miles up the river, high among the seaports of France. The Elbe and the Rhine, the giant rivers Mississippi and St. Lawrence, and many other rivers, have, as we all know, been wonderfully transformed by the hand of the engineer.

But land in turn, in this matter of transport, has encroached upon sea. In old days, when roads were few and bad, when there were no railways, and when ships were small, it was all-important to bring goods by water at all parts as far inland as possible. In England there were numerous flourishing little ports in all the estuaries and up the rivers, which, under modern conditions, have decayed. No one now thinks of Canterbury and Winchester in connection with seaborne traffic; but Mr. Belloc, in "The Old Road," a description of the historical Pilgrims' Way from Winchester to Canterbury, points out how these two old-world cathedral cities took their origin and derived their importance from the fact that each of them, Canterbury in particular, was within easy reach of the coast, where a crossing from France would be made; each on a river—in the case of Canterbury on the Stour just above the end of the tideway. In the days when the Island of Thanet was really an island, separated from the rest of Kent by an arm of the sea, and when the present insignificant river Stour was, in the words of the historian J. R. Green, "a wide and navigable estuary," Canterbury was a focus to which the merchandise of six Kentish seaports was brought, to pass on inland; it was in effect practically a seaport. Now merchandise, except purely local traffic, comes to a few large ports only, and is carried direct by rail to great distant inland centres. Reclus wrote that bays are constantly losing in comparative importance as the inland ways of rapid communication increase; that, in all countries intersected with railways, indentations in the coast-line have become rather an obstacle than an advantage; and that maritime commerce tends more and more to take for its starting-place ports situated at the end of a peninsula. He argues, in short, that traffic goes on land as far out to sea as possible instead of being brought by water as far inland as possible. He clearly overstated the case, but my contention is that, for human purposes, the coast-line, though the same on the map, has practically been altered by human agency. Ports have been brought to men as much as men to ports. We see before our eyes the process going on of bridging India to Ceylon so as to carry goods and passengers as far by land as possible, and in Ceylon we see the great natural harbour of Trincomalee practically deserted and a wonderful artificial harbour created at the centre of population, Colombo.

But let us carry the argument a little further. Great Britain is an island. Unless there is some great convulsion of Nature, to all time the Straits of Dover will separate it from the continent of Europe. Yet we have at this moment a renewal of the scheme for a Channel tunnel, and at this moment men are flying from England to France and France to England. Suppose the Channel tunnel to be made; suppose flying to be improved—and it is improving every day—what will become of the island? What will become of the sea?

They will be there and will be shown on the map, but to all human intents and purposes the geography will be changed. The sea will no longer be a barrier, it will no longer be the only high-road from England to France. There will be going to and fro on or in dry land, and going to and fro neither on land nor on sea. Suppose this science of aviation to make great strides, and heavy loads to be carried in the air, what will become of the ports, and what will become of sea-going peoples? The ports will be there, appearing as now on the map, but Birmingham goods will be shipped at Birmingham for foreign parts, and Lithgow will export mineral direct, saying good-bye to the Blue Mountains and even to Sydney Harbour.

Now, in saying this I may well be told by my scientific colleagues that it is all very well as a pretty piece of fooling, but that it is not business. I say it as an unscientific man with a profound belief in the limitless possibilities of science. How long is it since it was an axiom that, as a lump of iron sinks in water, a ship made of iron could not possibly float? Is it fatuous to contemplate that the conquest of the air, which is now beginning, will make it a highway for commercial purposes? We have aeroplanes already which settle on the water and rise again; we are following on the track of the gulls which we wonder at far away in the limitless waste of ocean. A century and a half ago the great Edmund Burke ridiculed the idea of representatives of the old North American colonies sitting in the Imperial Parliament; he spoke of any such scheme as fighting with Nature and conquering the order of Providence; he took the distance, the time which would be involved—six weeks from the present United States to London. If anyone had told him that what is happening now through the applied forces of science might happen, he would have called him a madman. Men think in years, or at most in lifetimes; they ought sometimes to think in centuries. I believe in Reclus's words, "All man has hitherto done is a trifle in comparison with what he will be able to effect in future." Science is like a woman. She says No again and again, but means Yes in the end.

In dealing with land and water I have touched upon natural divisions and natural boundaries, which are one of the provinces of geography. Flying gives the go-by to all natural divisions and boundaries, even the sea; but let us come down to the earth. Isthmuses are natural divisions between seas; the ship canals cut them and link the seas—the canal through the Isthmus of Corinth, the canal which cuts the Isthmus of Perekop between the Crimea and the mainland of Russia, the Baltic Canal, the Suez Canal, the Panama Canal. The Suez Canal, it will be noted, though not such a wonderful feat as the Panama Canal, is more important from a geographical point of view, in that an open cut has been made from sea to sea without necessity for locks, which surmount the land barrier but more or less leave it standing. Inland, what are natural divisions? Mountains, forests, deserts, and, to some extent, rivers. Take mountains. "High, massive mountain systems," writes Miss Semple, "present the most effective barriers which man meets on the land surface of the earth." But are the Rocky Mountains, for instance, boundaries, dividing-lines, to anything like the extent that they were now that railways go through and over them, carrying hundreds of human beings back and fore day by day? On what terms did British Columbia join the Dominion of Canada? That the natural barrier between them should be pierced by the railway. Take the Alps. The canton Ticino, running down to Lake Maggiore, is politically in Switzerland; it is wholly on the southern side of the Alps. Is not the position entirely changed by the St. Gothard tunnel, running from Swiss territory into Swiss territory on either side of the mountains?

If, in the Bible language, it requires faith to remove mountains, it is not wholly so with other natural boundaries. Forests were, in old days, very real natural dividing-lines. They were so in England, as in our own day they have been in Central Africa. Between forty and fifty years ago, in his "Historical Maps of England," Prof. C. H. Pearson, whose name is well known and honoured in Australia, laid down that England was settled from east and west, because over against Gaul were heavy woods, greater barriers than the sea. Kent was cut off from Central England by the Andred Weald, said to have been, in King Alfred's time, 120 miles long and 30 broad. Here are Prof. Pearson's words: "The axe of the woodman clearing away the forests, the labour of nameless generations reclaiming the fringes of the fens or making their islands habitable, have gradually transformed England into one country, inhabited by one people. But the early influences of the woods and fens are to isolate and divide." Thus the cutting down of trees is sometimes a good, not an evil, and there are some natural boundaries which man can wholly obliterate.

Can the same be said of deserts? They can certainly be pierced, like isthmuses and like mountains. The Australian desert is a natural division between Western and South Australia. The desert will be there, at any rate for many a long day after the transcontinental railway has been finished, but will it be, in anything like the same sense as before, a barrier placed by Nature and respected by man? Nor do railways end with simply giving continuous communication, except when they are in tunnels. As we all know, if population is available, they bring in their train development of the land through which they pass. Are these deserts of the earth always going to remain "deserts idle"? Is man going to obliterate them? In the days to come, will the desert rejoice and blossom as the rose? What will dry farming and what will afforestation have to say? In the evidence taken in Australia by the Dominions Royal Commission, the Commissioner for Irrigation in New South Wales tells us that "the dry farming areas are carried out westward into what are regarded as arid lands every year," and that, in his opinion, "we are merely on the fringe of dry farming" in Australia. A book has lately been published entitled "The Conquest of the Desert." The writer, Dr. Macdonald, deals with the Kalahari Desert in South Africa, which he knows well, and for the conquest of the desert he lays down that three things are essential—population, conservation, and afforestation. He points out in words which might have been embodied in Mr. Marsh's book, how the desert zone has advanced through the reckless cutting of trees, and how it can be flung back again by tree barriers to the sand dunes. By conservation he means the system of dry farming so successful in the United States of America, which preserves the moisture in the soil and makes the desert produce fine crops of durum wheat without a drop of rain falling upon it from seedtime to harvest, and he addresses his book "to the million settlers of to-morrow upon the dry and desert lands of South Africa." If the settlers come, he holds that the agency of man, tree-planting, ploughing and harrowing the soil, will drive back and kill out the desert. The effect of tree-planting in arresting the sand dunes and reclaiming desert has been very marked in the Landes of Gascony. Here, I gather from Mr. Perkins' report, are some 3600 square miles of sandy waste, more than half of which had, so far back as 1882,

been converted into forest land, planted mainly with maritime pines.

What, again, will irrigation have to say to the deserts? Irrigation, whether from underground or from overground waters, has already changed the face of the earth, and as the years go on, as knowledge grows and wisdom, must inevitably change it more and more. I read of underground waters in the Kalahari. I read of them too in the Libyan Desert. In the *Geographical Journal* for 1902 it is stated that at that date nearly 22,000 square miles in the Algerian Sahara had been reclaimed with water from artesian wells. What artesian and sub-artesian water has done for Australia you all know. If it is not so much available for agricultural purposes, it has enabled flocks and herds to live and thrive in what would be otherwise arid areas. Prof. J. W. Gregory, Mr. Gibbons Cox, and others have written on this subject with expert knowledge; evidence has been collected and published by the Dominions Royal Commission, but I must leave to more learned and more controversial men than I am to discuss whether the supplies are plutonic or meteoric, and how far in this matter you are living on your capital.

If we turn to irrigation from overground waters, I hesitate to take illustrations from Australia, because my theme is the blotting out of the desert, and most of the Australian lands which are being irrigated from rivers, and made scenes of closer settlement, would be libelled if classed as desert. Mr. Elwood Mead told the Royal Commission that the State irrigation works in Victoria, already completed or in process of construction, can irrigate more than 600 square miles, and that, if the whole water supply of the State were utilised, more like 6000 square miles might be irrigated. The Burrinjuck scheme in New South Wales will irrigate in the first instance not far short of 500 square miles, but may eventually be made available for six times that area. If we turn to irrigation works in India, it appears from the second edition of Mr. Buckley's work on the subject, published in 1905, that one canal system alone, that of the Chenab in the Panjab, had, to quote his words, turned "some two million acres of wilderness (more than 3000 square miles) into sheets of luxuriant crops." "Before the construction of the canal," he writes, "it was almost entirely waste, with an extremely small population, which was mostly nomad. Some portion of the country was wooded with jungle trees, some was covered with small scrub camel thorn, and large tracts were absolutely bare, producing only on occasions a brilliant mirage of unbounded sheets of fictitious water." The Chenab irrigation works have provided for more than a million of human beings; and, taking the whole of India, the Irrigation Commission of 1901–3 estimated that the amount of irrigated land at that date was 68,750 square miles; in other words, a considerably larger area than England and Wales. Sir William Willcocks is now reclaiming the delta of the Euphrates and Tigris. The area is given as nearly 19,000 square miles, and it is described as about two-thirds desert and one-third freshwater swamp. More than 4000 square miles of the Gezireh Plain, between the Blue and the White Nile, are about to be reclaimed, mainly for cotton cultivation, by constructing a dam on the Blue Nile at Sennaar and cutting a canal 100 miles long which, if I understand right, will join the White Nile, thirty miles south of Khartoum.

With the advance of science, with the growing pressure of population on the surface of the earth, forcing on reclamation as a necessity for life, is it too much to contemplate that human agency in the coming time will largely obliterate the deserts which now appear on our maps? It is for the young peoples of the British Empire to take a lead in—to quote a phrase from Lord Durham's great report—"the war with the wilderness, and the great feat of carrying water for 350 miles to Kalgoorlie, in the very heart of the wilderness, shows that Australians are second to none in the ranks of this war.

It is a commonplace that rivers do not make good boundaries because they are easy to cross by boat or bridge. Pascal says of them that they are "des chemins qui marchent" (roads that move), and we have seen how these roads have been and are being improved by man. "Rivers unite," says Miss Semple; and again, "Rivers may serve as political lines of demarcation, and therefore fix political frontiers, but they can never take the place of natural boundaries." All the same, in old times at any rate, rivers were very appreciable dividing-lines, and when you get back to something like barbarism, that is to say in time of war, it is realised how powerful a barrier is a river. Taking, then, rivers as in some sort natural boundaries, or treating them only as political boundaries, the point which I wish to emphasise is that they are becoming boundaries which, with modern scientific appliances, may be shifted at the will of man. In the days to come the diversion of rivers may become the diversion of a new race of despotic rulers with infinitely greater power to carry out their will or their whim than the Pharaohs possessed when they built the Pyramids. You in Australia know how thorny a question is that of the control of the Murray and its tributaries. There are Waterways Conventions between Canada and the United States. Security for the head-waters of the Nile was, and is, a prime necessity for the Sudan and Egypt. The Euphrates is being turned from one channel into another. What infinite possibilities of political and geographical complications does man's growing control over the flow of rivers present!

Thus I have given you four kinds of barriers or divisions set by Nature upon the face of the earth—mountains, forests, deserts, rivers. The first, the mountains, man cannot remove, but he can and he does go through them to save the trouble and difficulty of going over them. The second, the forests, he has largely cleared away altogether. The third, the deserts, he is beginning to treat like the forests. The fourth, the rivers, he is beginning to shift when it suits his purpose and to regulate their flow at will.

I turn to climate. Climates are hot or cold, wet or dry, healthy or unhealthy. Here our old friends the trees have much to say. Climates beyond dispute become at once hotter and colder when trees have been cut down and the face of the earth has been laid bare; they become dryer or moister according as trees are destroyed or trees are planted and hold the moisture; the cutting and planting of timber affects either one way or the other the health of a district. The tilling of the soil modifies the climate. This has been the case, according to general opinion, in the North-West of Canada, though I have not been able to secure any official statistics on the subject. In winter time broken or ploughed land does not hold the snow and ice to the same extent as the unbroken surface of the prairie; on the other hand, it is more retentive at once of moisture and of the rays of the sun. The result is that the wheat zone has moved further north, and that the intervention of man has, at any rate for agricultural purposes, made the climate of the great Canadian North-West perceptibly more favourable than it was. In Lord Strathcona's view, there was some change even before the settlers came in, as soon as the rails and telegraph lines of the Canadian Pacific Railway were laid. He told me that in carrying the line across a desert belt it was found that, within measurable distance of the rail and the telegraph line, there was a distinct increase of dew

and moisture. I must leave it to men of science to say whether this was the result of some electrical or other force, or whether what was observed was due simply to a wet cycle coinciding with the laying of the rails and the erection of the wires. I am told that it is probably a coincidence of this kind which accounts for the fact that in the neighbourhood of the Assouan dam there is at present a small annual rainfall, whereas in past years the locality was rainless. Reference has already been made to the effect of cultivation in the Kalahari Desert in increasing the storage of moisture in the soil. But it is when we come to the division between healthy and unhealthy climates that the effect of science upon climate is most clearly seen. The great researches of Ross, Manson, and many other men of science, British and foreign alike, who have traced malaria and yellow fever back to the mosquito, and assured the prevention and gradual extirpation of tropical diseases, bid fair to revolutionise climatic control. Note, however, that in our penitent desire to preserve the wild fauna of the earth we are also establishing preserves for mosquitos, trypanosomes and the tsetse fly.

Nowhere have the triumphs of medical science been more conspicuous than where engineers have performed their greatest feats. De Lesseps decided that Ismailia should be the headquarters of the Suez Canal, but the prevalence of malaria made it necessary to transfer the headquarters to Port Said. In 1886 there were 2300 cases of malaria at Ismailia; in 1900 almost exactly the same number. In 1901 Sir Ronald Ross was called in to advise; in 1906 there were no fresh cases, and malaria has been stamped out. Lesseps's attempt to construct the Panama Canal was defeated largely, if not mainly, by the frightful death-rate among the labourers; 50,000 lives are said to have been lost, the result of malaria and yellow fever. When the Americans took up the enterprise they started with sending in doctors and sanitary experts, and the result of splendid medical skill and sanitary administration was that malaria and yellow fever were practically killed out. The Panama Canal is a glorious creation of medical as well as of engineering science, and this change of climate has been mainly due to reclamation of pools and swamps, and to cutting down bush, for even the virtuous trees, under some conditions, conduce to malaria. Man is a geographical agency, and in no respect more than in the effect of his handiwork on climate, for climate determines products, human and others. Science is deciding that animal pests shall be extirpated in the tropics, and that there shall be no climates which shall be barred to white men on the ground of danger of infection from tropical diseases.

If we turn to products, it is almost superfluous to give illustrations of the changes wrought by man. As the incoming white man has in many places supplanted the coloured aboriginal, so the plants and the living creatures brought in by the white man have in many cases, as you know well, ousted the flora and fauna of the soil. Here is one well-known illustration of the immigration of plants. Charles Darwin, on the voyage of the *Beagle,* visited the island of St. Helena in the year 1836. He wrote "that the number of plants now found on the island is 746, and that out of these fifty-two alone are indigenous species." The immigrants, he said, had been imported mainly from England, but some from Australia, and, he continued, "the many imported species must have destroyed some of the native kinds, and it is only on the highest and steepest ridges that the indigenous flora is now predominant."

Set yourselves to write a geography of Australia as Australia was when first made known to Europe, and compare it with a geography now. Suppose Australia to have been fully discovered when Europeans first reached it, but consider the surface then and the surface now, and the living things upon the surface then and now. Will not man have been found to be a geographical agency? How much waste land, how many fringes of desert have been reclaimed? The wilderness has become pasture land, and pasture land, in turn, is being converted into arable. The Blue Mountains, which barred the way to the interior, are now a health resort. Let us see what Sir Joseph Banks wrote after his visit to Australia on Captain Cook's first voyage in 1770. He has a chapter headed "Some Account of that part of New Holland now called New South Wales." New Holland he thought "in every respect the most barren country I have seen"; "the fertile soil bears no kind of proportion to that which seems by nature doomed to everlasting barrenness." "In the whole length of coast which we sailed along there was a very unusual sameness to be observed in the face of the country. Barren it may justly be called, and in a very high degree, so far, at least, as we saw." It is true that he only saw the land by the sea, but it was the richer eastern side of Australia, the outer edge of New South Wales and Queensland. What animals did he find in Australia? He "saw an animal as large as a greyhound, of a mouse colour, and very swift." "He was not only like a greyhound in size and running, but had a tail as long as any greyhound's. What to liken him to I could not tell." Banks had a greyhound with him, which chased this animal. "We observed, much to our surprise, that, instead of going upon all fours, this animal went only on two legs, making vast bounds." He found out that the natives called it kangaroo, and it was "as large as a middling lamb." He found "this immense tract of land," which he said was considerably larger than all Europe, "thinly inhabited, even to admiration, at least that part of it that we saw." He noted the Indians, as he called them, whom he thought "a very pusillanimous people." They "seemed to have no idea of traffic"; they had "a wooden weapon made like a short scimitar." Suppose a new Sir Joseph Banks came down from the planet Mars to visit Australia at this moment, what account would he give of it in a geographical handbook for the children of Mars? He would modify the views about barrenness, if he saw the cornfields and flocks and herds; if he visited Adelaide, he would change his opinion as to scanty population, though not so, perhaps, if he went to the back blocks. He would record that the population was almost entirely white, apparently akin to a certain race in the North Sea, from which, by tradition, they had come; that their worst enemies could not call them pusillanimous; that they had some ideas of traffic, and used other weapons than a wooden scimitar; and he would probably give the first place in animal life not to the animal like a greyhound on two legs, but to the middling lamb, or perhaps to the ubiquitous rabbit. Australia is the same island continent that it always was; there are the same indentations of coast, the same mountains and rivers, but the face of the land is different. In past years there was no town, and the country was wilderness; on the surface of the wilderness many of the living things were different; and from under the earth has come water and mineral, the existence of which was not suspected. A century hence it will be different again, and I want to see sets of maps illustrating more clearly than is now the case the changes which successive generations of men have made and are making in the face of Australia and of the whole earth.

More than half a century ago Buckle, in his "His-

tory of Civilisation," wrote: "Formerly the richest countries were those in which Nature was most bountiful; now the richest countries are those in which man is most active. For in our age of the world, if Nature is parsimonious we know how to compensate her deficiencies. If a river is difficult to navigate, or a country difficult to traverse, an engineer can correct the error and remedy the evil. If we have no rivers we make canals; if we have no natural harbours we make artificial ones." These words have a double force at the present day and in the present surroundings, for nowhere has man been more active as a geographical agency than in Australia; and not inside Australia only, but also in regard to the relations of Australia to the outside world.

An island continent Australia is still, and always will be, on the maps. It always will be the same number of miles distant from other lands; but will these maps represent practical everyday facts? What do miles mean when it takes a perpetually diminishing time to cover them? Is it not truer to facts to measure distances, as do Swiss guides, in Stunden (hours)? What, once more, will an island continent mean if the sea is to be overlooked and overflown? The tendency is for the world to become one; and we know perfectly well that, so far as distance is concerned, for practical purposes the geographical position of Australia has changed through the agency of scientific man. If you come to think of it, what geography has been more concerned with than anything else, directly or indirectly, is distance. It is the knowledge of other places not at our actual door that we teach in geography, how to get there, what to find when we get there, and so forth. The greatest revolution that is being worked in human life is the elimination of distance, and this elimination is going on apace. It is entering into every phase of public and private life, and is changing it more and more. The most difficult and dangerous of all Imperial problems at this moment is the colour problem, and this has been entirely created by human agency, scientific agency, bringing the lands of the coloured and the white men closer together. Year after year, because distance is being diminished, coming and going of men and of products is multiplying; steadily and surely the world is becoming one continent. This is what I want geographers to note and the peoples to learn. Geographers have recorded what the world is according to Nature. I want them to note and teach others to note how under an all-wise Providence it is being subdued, replenished, recast, and contracted by man.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY PROF. E. G. COKER, M.A., D.Sc., PRESIDENT OF THE SECTION.

THE subject of stress distribution in materials, which I have chosen for this address, is not one which an engineer can claim as his peculiar province, for it has been and still is a fruitful field of investigation for the mathematician, the physicist, and the geologist, and has always been so since the commencement of scientific inquiry; indeed, it must have been the source of speculation and controversy ever since mankind emerged from a primitive state, and began to fashion dwellings, weapons, and tools from the materials at command.

The development of architecture from the earliest dwellings of savage races to the great temples of Egypt and Greece, the bridges and aqueducts of the Romans, and the mediæval buildings of Europe, all bear witness to the accumulation of practical knowledge of the properties of materials and of the stress distribution in structures, which we cannot fail to admire, although we know far too little of the way in which these ancient structures were planned and constructed. The magnificent arched and domed buildings of the Roman period, and the stately cathedrals of later times with their wealth of architectural form—tower and spire, flying buttress and vaulting—all show how considerable was the practical knowledge of stress distribution possessed by the master builders who planned and carried out these great structures. We, who inherit these buildings as a precious legacy of bygone ages, have at our command far greater resources in the accumulated knowledge of centuries of scientific discovery and invention, and can build more complex structures—great bridges of steel, towering frameworks covered by a thin veneer of masonry, and floating arsenals of the most bewildering intricacy. All these we can show to our credit as the result of the steady increase of scientific knowledge applied to practical ends, but, even now, knowledge of the stresses which come upon these complex structures and machines is relatively small. Scientific investigations of engineering problems of stress still lag behind constructive ability, and defective knowledge is obscured more or less by approximate theories and buttressed by factors of safety, which serve in one instance perhaps, but show in others that they have merely given a sense of fancied security with no real basis, and are more properly factors of ignorance, to be discarded at the earliest moment. Who, for example, can say with certainty what is the stress distribution throughout the compression members of a great bridge, built up of complicated steel shapes and plates, united by stiffening angles, gusset plates, and innumerable rivets. There is probably good reason for the belief that a great strut is relatively weaker than a small one, when both are designed according to the same approximate formulæ now used in current practice, and engineers are unwilling to take the responsibility for such members in a great structure, without providing a very ample margin of safety to cover the contingencies arising from lack of precise knowledge of the strength of these members. So numerous are the problems which arise in the design and construction of machines and structures, that it is perhaps not unprofitable to devote a short hour to the consideration of some of the available means which an engineer can use as a guide for his applications of science to construction, since of whatever kind are the professional activities he pursues, his place in the scheme of affairs mainly depends on his ability to make machines and structures for directing and modifying natural sources of power in known ways, or applying them to new purposes as scientific discoveries advance the boundaries of knowledge.

The power to do this depends, to no small extent, upon the ability to determine the distribution of stress in a structure, and the skilful manner in which material can be disposed for the required purpose.

It is of some help to our appreciation of the achievements of the great constructors of past ages, if we remember that they probably all held the erroneous view that materials of construction are perfectly rigid bodies, and, indeed, we know that as late as 1638 Galileo Galilei was of that opinion, and that he came to an entirely wrong conclusion as regards the stress distribution in a loaded cantilever.

It required the genius and insight of Robert Hooke to make a really great step, with his celebrated theory of the linear relation of stress to strain, and we can appreciate the glow of pride and satisfaction which he must have felt at his great discovery, when he records in 1675 that "his Majesty was pleased to see

the experiment that made out this theory tried at Whitehall, as also my spring watch."

Hooke had, in fact, discovered the fundamental principle upon which a theory of the elasticity and strength of materials could be based, and it would be interesting to trace the great advances which were rapidly made from this new vantage ground, whereby the main facts of the distribution of stress in simple members of structures became known, and a foundation was laid for the great advances of the mathematical theory. If I am silent upon the enormous developments of the modern theory of the strength of materials it is not from lack of appreciation, but because I do not deem myself adequately fitted to discuss the great work of the elasticians, which all engineers admire, and so few are equipped to follow with the full battery of mathematical tools which have been pressed into service in the pursuit of this great science.

Among the greatest of the services rendered by early pioneers was that of Young, who was the first to notice that the elastic resistance of a body to shear was different from its resistance to extension or contraction, and this led him to define a modulus of elasticity for materials in compression. As Prof. Love remarks, "This introduction of a definite physical concept, which descends, as it were, from a clear sky on the readers of mathematical memoirs, marks an epoch in the history of the science."

From the viewpoint of the engineer, nothing is of more practical importance than the great discoveries of Hooke and Young, that bodies like metal, wood, and stone are "springy" and have a simple linear relation between stress and strain. It is probably within the mark to say that nine-tenths of all the experimental investigations on stress distributions in structures have been entirely based on the fundamental principles which they enunciated, and new uses are continually arising. The recent application of the steam turbine to the propulsion of ships produced a profound change in marine-engine practice, and incidentally involved an entire reconstruction of methods for obtaining the horse-power developed, which had been gradually perfected from the time of Watt, but were absolutely useless for the new system of propulsion. Hooke's discovery of the essential springiness of metals enabled engineers quickly to devise new instruments capable of accurately measuring the infinitesimal angular distortions of propeller shafts, and from these to determine the horse-power transmitted by the aid of an appropriate modulus.

The construction of tall buildings affords another example where advantage has been taken to determine the loads upon columns by measuring the minute diminutions of length as the structure proceeds, thereby affording a valuable check upon the calculations for these members, and a trustworthy indication of the pressures supported by the foundations.

The distribution of stress in buildings constructed of composite materials like concrete reinforced with steel has also been examined by similar methods, and much data for guidance in future constructional work has been obtained, especially in the United States of America.

The still more difficult problems involved in the determination of the stresses in joints and fastenings of complicated structures have often been investigated by purely mechanical measurements of strain, and the experimental investigations of Profs. Barraclough and Gibson and their pupils upon the distribution of stress due to riveted joints and curved plates of boiler shells afford a notable example of the successful application of the measurement of small strains to a stress problem of great complexity.

That "science of measurement" is here sufficiently obvious, and it seems only due to the memory of that great engineer, Sir Joseph Whitworth, to refer to his great mechanical achievements of a true plane and well-nigh perfect screw, which enabled him to measure changes of one-millionth of an inch, and thereby gave experimental investigations of strains of a new impetus, which is reflected in subsequent work on the subject. Nor must we forget the no less important exposition, by Kelvin and Tait, of the scientific principles of instrument construction which have done so much for the design of instruments for the precise measurement of strains.

Mechanical measurements cannot, however, completely satisfy all our modern requirements, since they are essentially average values, and fail to accommodate themselves to many of the problems which press for solution.

In the quest for exact experimental knowledge, the measurement of stress at a point becomes of paramount importance, and we may, therefore, inquire what further means the researches of pure science have placed at our disposal for the determination of stress distribution in materials.

It is well known that many materials when tested to destruction show a considerable rise of temperature at the place of fracture, especially in very ductile materials; but Weber was the first to discover that a metal wire when stretched within the elastic limit is cooled by the action of the load, and this result was deduced later from the laws of thermo-elastic behaviour of materials by Lord Kelvin, who showed that tension and compression loads produce opposite effects, and that materials which have the property of contracting with rise of temperature show thermal effects of the reverse kind. Although the changes of temperature produced by stress are small within the elastic range—less than 1° C. for most materials—yet their effect upon a thermo-couple is readily measurable if the equilibrating effects of surrounding bodies are neutralised or allowed for, so that stress distribution can be determined by thermal measurements at a point. The correction for such disturbing causes is usually an important factor, and is generally so large that experimental work is more suitable for the laboratory than the workshop; but if all necessary precautions are taken a linear relation of stress to strain can be shown to hold up to the elastic limit of the material, while above this point the breakdown of the structure causes a rise of temperature of so marked a character that it has been utilised by several investigators as an indication of the yield point.

Experiments upon members subjected to tension, compression, and bending, show that thermal phenomena afford trustworthy indications of the stress in materials so diverse as a rolled-steel section, a block of cement, and beams of stone and slate. Although no attempt appears to have been made to investigate stress distributions of any great complexity, it seems not unlikely that thermal methods of investigation will ultimately prove of considerable value.

The transparency of metals to Röntgen rays is another phenomenon which has often been suggested as likely to be of service for work on stress distribution in materials, and Mr. Howgrave Graham and I have examined a number of rolled metals under stress up to the breaking point, without, however, discovering any change in the appearance of the material as seen on a fluorescent screen. Although our experiments showed no perceptible change, it is, of course, not impossible that an effect may have escaped our notice.

Another and still more fascinating field of research on stress distribution is afforded by the doubly refrac-

tive properties of transparent bodies under stress, a discovery made by Sir David Brewster almost exactly one hundred years ago, and but rarely made use of since by engineers, although Brewster himself immediately saw its value for experimental purposes, and suggested that models of arches might be made of glass, and the effects of stresses due to loading rendered visible in polarised light.

Brewster carried his investigations further, by the invention of a "chromatic teinometer" for investigating the nature of strains, and consisting of plates or bars of glass subjected to flexure in definite ways for comparison with the body under stress.

At a much later date (1841) Neumann developed an elaborate theory for the analysis of strain in transparent bodies due to load, unequal temperature, and set, while, still later, the youthful genius of Clerk-Maxwell supplied an algebraical solution for the stress distribution in any plate subjected to stresses in its own plane.

The early history of the development of this branch of science is, in fact, remarkable for notable contributions at long intervals of time, and the almost complete disregard by engineers of its practical importance.

The application of optical investigation to the determination of stress distribution in engineering structures and machines has, however, been hindered by causes which, although apparently insignificant, have been very real obstacles, and among these was the absence of a transparent material which could be fashioned into shapes suitable for investigating technical problems. It is not an easy matter, for example, to construct a glass model of a bridge free from internal stress, in the manner suggested by Brewster; and, moreover, glass is extremely fragile under load, especially in cases where the stress distribution in it varies very much, while the cost of construction is very great. Happily there is now no necessity to employ glass for experimental investigation on engineering problems, since modern chemistry has supplied artificial bodies, such as the nitro-cellulose compounds used for many trade purposes, which have optical properties very little inferior to glass, are able to bear great stresses without injury, and also are capable of being fashioned with the ease and certainty of a wooden model. Photographic processes are also able to reproduce the brilliant colour effects caused by stress in transparent materials, so that permanent records can now be made for future reference.

The construction of polariscopes for examining models on a large scale is very essential for technical research, and the great scarcity of Iceland spar of sufficient purity and size for use as Nicol's prisms has caused much attention to be paid to the construction of apparatus for producing plane polarised light by the aid of sheets of glass. Fortunately this presents little difficulty, and although the light is not nearly so well polarised as that obtained from a Nicol's prism it is sufficiently so for the purpose. Large quarter-wave plates of mica have also been constructed by my colleague, Prof. Silvanus Thompson, for obtaining circularly polarised light, and these have proved sufficiently exact and exceedingly useful for large models.

It is of importance to show that the stress distribution revealed by a polarised beam of light passing through an elastic transparent material in no way differs from that obtained by other means, and evidence is available in modern researches, especially by Filon, that the experimental results obtained with glass agree with those of the theory of elasticity, while a satisfactory agreement of a similar kind has also been obtained with nitro-cellulose compounds, although not in so complete and direct a manner. Such an agreement may be expected on theoretical grounds, since the values of elastic constants do not affect the fundamental equations for stresses in a plane, and although for three-dimensional stress the effect of the stretch-squeeze ratio causes some difference, yet this is usually negligible.

Most of the physical constants of glass have been determined with very considerable accuracy, but other transparent substances have so far received little attention, and their optical constants are not well known. The stress-strain relations of glass and nitro-cellulose have been determined with considerable accuracy, and a useful idea of their relation to metals may be gained from the value of the stretch-modulus, E, and the stretch-squeeze ratio, σ.

The accompanying table shows some average values for a few important materials, and it is of interest to note that the stretch-squeeze ratios of cast-iron and plate-glass are very similar, while the values of the stretch modulus are nearly as three to two. These two materials also possess other like characteristics: they are both very brittle, and possess well-developed crystalline structure, so that we may expect the properties of cast-iron under stress to be very faithfully followed by plate-glass.

Material	E	σ
Steel ...	30,000,000 ...	0·25
Wrought iron ...	28,000,000 ...	0·28
Cast iron ...	15,000,000 ...	0·25
Plate-glass ...	10,500,000 ...	0·23
Nitro-cellulose ...	260,000 to 300,000 ...	0·40

The high values of the stretch modulus for steel and wrought iron are not, apparently, approached by any transparent material having similar ductile properties, but although nitro-cellulose has a stretch modulus of rather less than one-hundredth that of steel, its stress-strain properties are not unlike. In some recent experiments with a miniature testing machine fitted with an arrangement for recording the stress-strain relations of xylonite throughout the whole range of stress up to fracture, the main characteristics of steel appear on a very reduced scale, and give additional confidence that the results of optical experiments on this material are applicable to metal structures.

The complete analysis of stress distribution in a plate is not, however, a simple matter, and the analysis of Clerk-Maxwell was intended to provide a solution based on the properties of the isochromatic and isoclinic lines, coupled with the law that the optical effect is proportional to the difference of the principal stresses at a point, and to the thickness of the plate.

A principal stress perpendicular to the bounding planes is assumed to have no optical effect; but since many cases have arisen where there are three principal stress components, it seemed desirable to examine such a case experimentally.

It is a matter of some difficulty to arrange apparatus to stress a specimen in the direction of the incident beam, and at the same time observe the optical effect free from disturbing causes, since a transparent medium must be interposed for applying the required load, and this will be subject to stresses which may interfere with the optical effect on the specimen.

Some observations on circular plates clamped at the edges and uniformly loaded over one face, showed that the bending stresses produced in the plate caused very little optical effect, since the tension and compression stresses neutralised one another, while the shear effects also appeared to be practically negligible. The only remaining stresses of importance were those caused by the clamping plates at the boundary, which produced radial and circumferential stresses having

circular symmetry, and as the optical effects of these latter disappeared at a small distance from the edge, a field of view was obtained in which the optical effects of load applied perpendicularly to the plate were quite small, even when the internal stresses were very great.

Two circular plates clamped together to enclose a space between them may therefore be used as windows for observing the effect of a uniform pressure upon a transparent specimen, which latter may be a plate with its faces parallel to the end plates closing the chamber. If cubical compression is applied by a fluid, the principal stresses in the plane of the plate produce opposing optical effects, and any remaining effect is due to perpendicular pressures on the faces. The arrangement of experimental apparatus, therefore, took the form of a pair of transparent windows separated by an annular disc, and firmly clamped together by collars. The central chamber so formed was subjected to pressure of air, or other fluid, up to about one thousand pounds per square inch, and afterwards the specimen was introduced and the same pressure applied; but no visible change of effect could be observed. Finally, the specimen was set in the field of view outside the chamber, and pressure again applied by the fluid, but still no change was apparent. In all three cases the optical effects produced were small, and practically alike, so that the experimental evidence appears to warrant the conclusion that a principal stress in the direction of an incident beam of polarised light has no optical effect in a thin plate, or at any rate is so small that it may be neglected.

That the retardation between the ordinary and extraordinary rays is proportional to the stress difference perpendicular to the incident beam within the elastic limit of the material may, therefore, be taken as reasonably accurate, although future research may show that it is only an approximation, or even that it is more accurate to commence from a fundamental strain equation; but according to present knowledge there appears to be no warrant for such a procedure.

A more pressing difficulty arises with regard to the optical constant connecting the wave-length retardation with the stress difference. The recent researches of Filon on glass show that the value of this constant is curiously dependent on the previous history of the material, especially as regards its heat treatment. Until further knowledge is gained on this matter it appears to be necessary to guard against errors in stress measurement from this cause by a careful selection and treatment of the material used, since for other artificial bodies we may find that the variation in the constant is not less in magnitude, and is at least as complex as in glass. In some instances the stress optical coefficient may be dispensed with, and Filon has shown, in cases where a theory of stress distribution has been worked out and it is desired to compare it with the results of optical measurements, that the isoclinic lines offer many advantages, since they are independent of photo-elastic constants, and the material need only be subjected to small stresses.

The experimental analysis of stress distribution in a body depends on the possibility of finding the magnitudes and directions of the principal stresses at every point, and in practice it is found the simplest plan to determine the directions of stress from the lines of equal inclination obtained in plane polarised light, and to measure the stress difference by comparison with a wave-length standard, such as a Babinet compensator, or by comparison with a simple tension member set along one of the lines of principal stress, and loaded until the total effect produced is a dark field denoting a zero value. The difference of the principal stresses is then measured in terms of a simple tension. This alone is insufficient to determine the distribution, unless one of the principal stresses is zero, and, in general, another independent measure must be obtained. This is very conveniently supplied by the change in the lateral dimensions of the plate under stress, since this change may be taken, in the absence of a third principal stress, as proportional to the generalised sum of the principal stresses throughout the thickness.

The determination of the lateral strains in a comparatively thin plate, forming part of a model of a machine or structure, necessitates measurements of extremely minute linear quantities. If, for example, a plate of xylonite is taken, of the maximum thickness obtainable for optical work, a simple calculation shows that these strains must be measured to an accuracy of one- or two-millionths of an inch. Several instruments have been designed and constructed for this purpose, to fulfil conditions which appear to be essential for successful use. It is necessary to avoid all chance of injury to the surface of a transparent material, so that the measuring points of an instrument can only be pressed lightly against the surfaces, and the weight must, therefore, be supported independently of the model. In instruments so far constructed, the measuring mechanism is carried on a **U**-shaped frame, for convenience of movement from point to point of the specimen. One measuring needle is secured and operated by a calibrating screw, and the other is free to move a multiplying lever system, and thereby tilt a mirror to give an angular deflection, which latter is calibrated by reference to the standard screw when the instrument has been finally secured in place. In recent work the labour of accurately setting the instrument in a number of different positions has proved so great, that my assistant, Mr. F. H. Withycombe, has designed a useful adjunct in the form of a mechanical slide-rest, to effect the required changes easily and expeditiously. In one arrangement, a bracket carries the measuring instrument on a three-point support, and movement is effected by slides arranged to give displacements along three axes at right angles, and their amounts are measured by micrometer screws to an accuracy of rather less than one-thousandth of an inch.

These methods of stress determination avoid the difficulties of the Clerk-Maxwell analysis, which necessitates the determination of the equations to both families of isochromatic and isoclinic bands, usually a mathematical problem of considerable complexity. In some simple cases Mr. Scoble and I have verified the accuracy of the method of lateral measurements for determining the sum of the principal stresses, by comparing the calculated stresses with the experimental values obtained in a plate of transparent material. We have lately carried these experiments a stage further, and have shown that the measured sums of the principal stresses in steel agree with the calculated values. This experimental solution, in fact, gives the stress at a point in a plate, if the conditions are those assumed by the mathematical case of a plate where generalised equations of stress apply.

It is at once obvious, if the utility of experiments on models of this kind is admitted, that experimental evidence is available on a variety of practical engineering problems covering a very wide field of practice, not merely qualitative, but quantitative, and approximating to the needs of the physicist and mathematician, and well within the known variations of the materials with which the engineer has to deal in his daily practice.

During the last few years much attention has been paid to the determination of the stresses in structural elements of primary importance, but only a small

number of cases have been examined, since even the simplest problems have proved somewhat difficult, and much time and labour have been spent in perfecting optical and mechanical appliances to suit the special conditions required for investigations on transparent models. A simple example of a case easily examined and of practical importance is that of a tension member subjected to an eccentric load. The optical effects here show a linear distribution of stress due to the combination of direct pull and bending, while the neutral axis moves towards the tension side as the stress increases. Not only can these effects be measured, but if the specimen begins to fail some indication is obtained of the way in which the stress distribution is changed to meet the new conditions, and there is found a tendency to an equalisation of the maximum stress at the boundary, although at present the form of the curve of distribution beyond the elastic limit is largely conjectural.

A case like that of a very short member subjected to direct compression is also not without interest, partly because it reveals unexpected difficulties. In the first place it is not easy to apply a pure compression stress, and if the surfaces in contact are not of the same materials it appears to be practically impossible, since the lateral changes are unlike, and shear stress is therefore produced at the plane of the surfaces in contact. In a short member this shear has a very important influence, and by interposing a thin layer of a material, such as india-rubber, between the pressure plates and the short transparent block, the artificial shear effect produced by the india-rubber is easily shown to influence the distribution throughout, and to increase the stress in a very marked way. Experiments on transparent materials show that the increase of stress may be twenty per cent. or even more. Such an effect is known to take place when cubes of stone are crushed between lead plates, and optical investigations on models have enabled a quantitative measure of the effect to be ascertained in this and other cases, thereby confirming the theoretical investigations of Filon on the distribution of stress in such members under various practical systems of loading.

The local effects produced near the points of application of a load are usually of considerable importance, and their influence on the stress distribution in beams has been examined by Carus-Wilson.

The stress effects produced by discontinuities in materials is also of considerable interest, and the cases arising from the necessities of construction are infinite in their variety.

The practical importance of an accurate knowledge of the change in stress distribution produced by changes of section in a member is so thoroughly appreciated that it needs no insistence, and it has received much attention from a mathematical point of view. Thus the local effect of a spherical cavity in a member subjected to uniform tension or compression load has been shown by Love to double the intensity very nearly, while Kirsch has shown that a small cylindrical hole in a tension member trebles the stress intensity. If the hole is elliptical the increase of stress may be still greater, and Inglis has shown, among other interesting cases, that if the minor axis of the ellipse is parallel to the direction of the applied load in a tension member, the stress intensity is increased by an amount measured by twice the ratio of the axis of the ellipse.

A crack, considered as the limiting case of an elliptical hole, is thus seen to give extremely great stresses at the ends, tending towards infinite values for an extremely fine crack.

Optical experiments afford an independent means of examining the alterations of stress intensity produced by discontinuities, and the results are found to agree remarkably well with those obtained from the theory of elasticity. The stress at the boundary of a small cylindrical hole in a plate has been found to be almost exactly three times the stress in the full plate, and the effects of holes comparable with the width of the tension member have also been examined in some detail.

In the case of a rivet just filling the hole and exerting no tangential effect at the boundary there is a lessened tension stress across the minimum section at the boundary hole, accompanied by a marked radial tension. These effects have been recently confirmed in a mathematical discussion by Suyehiro. Other cases give satisfactory agreement with calculation, and we may therefore feel some confidence that experimental investigation will prove useful in some of the very complicated cases arising out of engineering practice where analysis is difficult, if not impossible.

The effects of overstress in materials may also be examined by optical means, and although the laws relating to stress distribution in overstressed transparent material are not known, the general effects observed in simple cases are fairly evident. If, for example, a tension member of glass is stressed, there is no ductile yielding of the material, and the stress will therefore rise very rapidly at the boundary of a small hole, and fracture will therefore occur with a moderate load. If, however, a ductile transparent material is employed, and the material shows signs of failure at the hole, the breakdown of the structure spreads outwards as the load is increased, until we may have a condition in which within the elastic limit the curve of stress intensity at the minimum section accords with calculation, but at the overstressed part the stress tends to equalise, and the curve of intensity tends to become horizontal near the hole. The mean value of this part of the stress distribution may be inferred from the difference between the total load and the measured values below the region of failure; but the true distribution of the overstress has not been accurately determined, so that the shape of this peak is largely conjectural.

The effects of groups of rivets such as occur in bridges, boilers, and structural members of all kinds, afford ample scope for further inquiry; but before more exact knowledge can be gained of the condition of stress in a complicated riveted joint it appears necessary to examine thoroughly the very simple cases.

Mr. Scoble and I have examined the case of the load applied by one rivet to a plate with various amounts of overlap, and the stresses around the rivet holes had been measured with fair accuracy.

Other interesting cases of discontinuity in structure are afforded by the engine hatchways, gun-turrets, funnel openings, and the like, in ships' decks, and some progress in this direction has been made by experiments on model decks, subjected to loads like those produced when a vessel meets the waves due to a head sea.

Even if the utility of transparent models is left out of account, it is generally acknowledged that many engineering problems are often simplified by the use of models of machines and structures on a small scale, when circumstances forbid experimental examination of the actual work. No defence of their use is, I think, necessary, since the employment of models is a characteristic feature of British methods, not limited to engineers. Kelvin did not disdain their use, and his successors, who have done so much to advance knowledge of the æther and the atomic dust, have freely employed their great ingenuity in

the construction of mechanical models and diagrams to explain their views, as in the Lodge cog-wheel diagrams of the æther, the planetary systems of atoms of J. J. Thomson and Rutherford, and the grouping of elements by Soddy.

Engineers have not the same great difficulties which confront those who are advancing the boundaries of pure science; their models are very much what they please to make them; but, even then, problems arise which are sufficiently difficult to tax all the resources of applied science. The behaviour of models considered as similar structures is, therefore, a subject which engineers are bound to investigate in order to determine the effects of fixed and moving loads, the action of wind, the pressure and frictional effects of steam and other fluids, and many other problems.

In the majority of cases the simplest and most direct method is the experimental study of a model, from which to obtain the data required for calculating effects on a full-sized structure, and hence the laws of similarity have received a very close scrutiny.

Although most valuable information can be obtained from models, their usefulness is clearly limited. The effects of the dead weight of a structure are proportional to the cube of the linear dimensions, and are, therefore, not usually measurable on a model except in exceptional circumstances, as, for instance, where elastic jellies are employed, as in the well-known investigations of Pearson on the stress distribution in reservoir dams. Nor are questions of stability easy to solve, since the forces producing instability are proportional to the size of the model. On the other hand, stress effects due to applications of load may be measured by the strains produced in a model of the same material, if the loads are proportional to the squares of the linear dimensions. The effects of applied load are studied even better in a model constructed of transparent material, since the variation of stress from point to point can be studied with much greater ease and certainty.

As detailed models of this latter kind present some variations from the usual laws of similarity, it may be of interest to indicate their nature. Questions of deformation clearly involve the elastic constants of the transparent material and their relation to those of the proposed structure, while stress distribution in the solid is influenced by the value of Poisson's ratio. This latter effect is quite small for glass, but may become appreciable with other substance. It is negligible in a model of any material which approximates to a thin plate stressed by forces in its own plane.

The optical effects for any given load are, moreover, independent of the thickness of the material, and depend upon the stress difference, so that colour effects are obtained which may be regarded as pictures of shear stress throughout the model. Modern researches on ductile materials like structural steel indicate that such materials fail at some limiting value of shearing stress, and since the place where these limiting values are reached in the model are visible to the eye, the weak places in the design of a structure can be ascertained and a faulty design corrected by purely experimental means.

In this connection it is of interest to mention that M. Mesnager, the chief engineer of bridges and roads to the French Government, has recently constructed an elaborate model in glass of a design of an arched bridge of about 310 feet span. This investigation was considered advisable for a work of this magnitude constructed of reinforced concrete, in order to check the calculations, especially of maximum stresses in the arched ribs, which latter were assumed to be fixed at the ends.

The effects of reinforcements were allowed for by determining equivalent sections of glass for the members of the model. Many difficulties had to be overcome in the production of a model free from optical defects, but these were all successfully surmounted. The stresses in the model were determined by aid of a Babinet compensator, and formed a valuable check upon the calculations for a structure of this great magnitude and somewhat unusual design.

In this brief and incomplete account of a small branch of applied science relating to engineering the fundamental importance of discoveries in pure science is manifest.

The discoveries in pure science and their innumerable applications to practical ends are ever a potent factor working for the common good, and the value which the British Association places upon applied science was most cordially voiced by Prof. Bateson in his Portsmouth address when he said: "To the creation of applicable science the very highest gifts and training are well devoted," and, "The man who devotes his life to applied science should be made to feel that he is in the main stream of scientific progress. If he is not, both his work and science at large will suffer. The opportunities of discovery are so few that we cannot afford to miss any, and it is to the man of trained mind, who is in contact with the phenomenon of a great applied science, that such opportunities are most often given"; and, again, "If we are to progress fast there must be no separation between pure and applied science. The practical man with his wide knowledge of specific natural facts, and the scientific student ever seeking to find the hard general truth which the diversity of Nature hides—truths out of which any lasting structure of progress must be built—have everything to gain from free interchange of experience and ideas."

Engineers who are more immediately concerned with the problems of directing the great sources of power in Nature for the use and convenience of man are indeed grateful to our president for these inspiring words, and trust that the ties which unite investigators in pure and applied science will never slacken, but will knit together more closely for a joint advance to a more perfect understanding and utilisation of the laws of Nature.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

SHEFFIELD.—The council has decided to invite Dr. J. B. Leathes, F.R.S., professor of pathological chemistry in the University of Toronto, to accept the chair of physiology rendered vacant by the acceptance of Prof. J. S. Macdonald of the chair of physiology in the University of Liverpool.

A COPY of the calendar for the forthcoming session of the City of Bradford Technical College has been received. It provides full particulars of the various day courses arranged, prospectuses of the evening courses in different departments, and general guidance for intending students. The diploma of the college is awarded to each day student who has been in attendance for three complete sessions subsequent to passing the entrance examination, and has passed the college examinations in ali subjects of the diploma course taken. The diploma courses in chemistry and in chemistry and dyeing extend over four years. The diploma courses afford a full training for the various branches of the textile, chemical, and engineering industries. Arrangements have been made with the

University of Leeds whereby students of the University or of the college have the use of certain equipment and other facilities at both institutions. Students remaining for a fourth year may take up advanced studies or research in a large number of branches of technological science. The associateship of the college, which confers several privileges, is awarded to certain students who, holding the college diploma, have attained their majority, had a year's practical experience with a firm engaged in their trade or profession subsequent to obtaining the diploma, and have submitted an approved original thesis.

THE calendar for the forthcoming session—the one hundred and nineteenth—of the Royal Technical College, Glasgow, is now available. It will be remembered that in 1913 the college became affiliated to the University of Glasgow. A university advisory joint-committee has been established, and a joint-board of studies in applied science and joint-boards of examiners in the same department representative of the university and the college, have been constituted. Candidates for the degree of B.Sc. in applied science may attend the necessary qualifying courses either in the university or in the college or in both, provided that the fees paid for graduating courses in the college are not less than those payable for corresponding courses in the university. The courses of study provided by the college in civil, mechanical, electrical, and mining engineering include the classes necessary for graduation in applied science. The University of Edinburgh has recognised the day classes of the college as qualifying for its degree of B.Sc., under certain regulations. Among other interesting arrangements explained in the calendar that may be mentioned by which a large number of engineering firms have expressed their willingness to allow a selected number of their apprentices facilities for carrying out a scheme of college study conjoined with practical work. The courses of study in engineering are held during the winter session of the college, and thus student-apprentices are left free to spend the intervening summers in works. The college provides practical instruction in all branches of technology, and the calendar gives full particulars of all for the use of intending students.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 24.—M. P. Appell in the chair.—B. **Baillaud**: Observations of the eclipse of the sun of August 21 made at the observatories of Algiers and Paris. At Algiers the eclipse was observed under good conditions. Thirty photographs were obtained, times of contact measured, and the ionisation studied. At Paris measurements were made of times of contact and four negatives were taken, but clouds interfered with the observations.—H. **Deslandres** and A. **Perot**: A second series of attempts to obtain a maximum magnetic field. The use of water with a new mode of cooling. The authors have aimed at the use of intense currents and large quantities of electrical energy rather than applying enormous masses of iron. The essential difficulty is the cooling of the bobbins carrying the high current, and an apparatus for effecting this with a current of water is described and illustrated. The maximum field obtained was 63,700 gauss, 22,900 of which was due to the iron core. The current used was 5000 amperes. A field of 50,000 gauss was obtained without an iron core (energy 340 kilowatts). The possibility of obtaining still higher fields by this method of winding and cooling is discussed.—M. **Bezssonoff**: The pigments of Fusarium. Two pigments are present: one yellow, belonging to the anthocyanic group; the other red, identified with carotine, described by Wildstäter.—E. **Maurié**: The nutritive value of ossein. The nitrogenous material contained in bones is of considerable nutritive value. Details of the mode of extraction are given.—J. **Danysz**: The treatment of trypanosomiasis by arsenical compounds, combined with salts of silver and antimony (products 88^2 and 102^i). The compound specially studied had the composition

$$[C_{12}H_{12}.O_2N_2.As_2].AgBr.SbO(H_2SO_4)_2,$$

and showed marked improvement in therapeutic properties against *Tr. surra* and *Tr. gambiense* as compared with compounds previous tried. In the case of the mice used for the experiments the fatal dose (per 20 grams) was 5 mgr., the tolerated dose 0·4 mgr. The ratio between the tolerated dose and the curative dose was 80 : 1 for *surra* and 100 : 1 for *Tr. gambiense*. Confirmative experiments were carried out on rabbits.—J. M. **Barbosa**: The bronchial sphincters in *Delphinus delphis*.

THE CRETACEOUS FLORA.

Catalogue of the Mesozoic Plants in the British Museum (Natural History). The Cretaceous Flora. Part i., Bibliography, Algæ and Fungi. By Dr. Marie C. Stopes. Pp. xxiii + 285 + ii plates. (London: British Museum (Natural History): Longmans, Green and Co., 1913.) Price 12s.

DR. MARIE STOPES set herself a severe task in deciding to include in the catalogue of Cretaceous plants an exhaustive bibliography and list of species. The list of species from Cretaceous beds, described up to December 31, 1910, occupying nearly two hundred pages, affords a striking illustration of the large amount of material in palæobotanical literature that serves no useful purpose. While acknowledging that a list of this kind is valuable as a source of information, it is difficult to repress a certain suspicion that the result obtained is scarcely a fair return for the labour expended. As Dr. Stopes continues her investigations the value of the list will be considerably increased by the addition of critical remarks on such of the records as come under her purview. As it stands the catalogue of names may mislead the unwary who have not learnt by experience to regard with distrust a large proportion of determinations based on fragments of fossil Angiosperms; but as a storehouse of bibliographical information the list will be of real service to students. In the Introduction Dr. Stopes gives a useful summary of literature dealing with Cretaceous floras, and the stratigraphical table is a particularly welcome contribution which will do much to clear up the confusion caused by the adoption of different terms for subdivisions of the Cretaceous system in different countries. The publication of a list of dates of the parts of Brongniart's "Histoire des végétaux fossiles" is a much needed step towards a greater uniformity in systematic work: in the preparation of this bibliographical note the author expresses her indebtedness to Mr. C. Davies Sherborn.

The latter part of the catalogue is concerned with descriptions of Cretaceous thallophyta, in many instances accompanied by helpful illustrations. The author restricts the use of the generic name Algites, proposed in 1894 in a comprehensive sense for fossils which cannot be referred with any degree of certainty to a particular recent genus or family, to *flattened* impressions, and employs Sternberg's designation Chondrites for "algæ, or fossils which suggest algæ, with a much-branched dichotomous or sympodial thallus which is *cylindrical*." Having regard to the worthlessness, from the point of view of relationship to Chondrus, of most of the fossils referred to Chondrites, it would seem preferable to discard the name in favour of a general designation such as Algites if used in the wider sense in which it was first proposed. The concise summary of the characters of several types of algæ belonging to the Siphonaceæ and the Rhodophyceæ will serve to direct attention to the possibilities of a neglected branch of palæobotanical research. Among the fungi included in the catalogue the two most interesting are the Japanese species, *Pleosporites shirainus* and *Petrosphaeria japonica,* the former being represented both by perithecia and septate vegetative hyphæ.

Dr. Stopes carries into practice her suggestion (*Annals of Botany,* 1911) that "all fossil plants for which there is no good, scientific reason for association with given families and genera, and to which, nevertheless, names indicative of such affinities have been given, should be printed henceforth in Gothic characters." If this plan were adopted in the list of Cretaceous species in the first part of the volume as well as in the descriptive portion, very serious demands would be made on the printer's Gothic fount. It is doubtful whether this method will find favour: the use by palæobotanical writers of designations implying affinities that are assumed on wholly insufficient grounds seriously detracts from the value of published lists; but, it may be urged, the better course would be to discard the misleading names rather than to dignify them by the employment of Gothic letters. Moreover, this attempt to institute an *Index Expurgatorius* is based on an individual opinion and has not the sanction of supreme authority.

Dr Stopes has made an excellent beginning: the less interesting and more laborious work has been accomplished, and we confidently expect that the later volumes will add greatly to our knowledge of the vegetation of a period which is of exceptional importance. The flora of the preceding Wealden period is, in its general facies, a continuation of the Jurassic floras: flowering plants had undoubtedly been evolved, but they occupied a subordinate position and, so far as we know, were unrepresented in the Wealden flora of Britain. It was in the succeeding stages of the Cretaceous system that this remarkably successful group rapidly rose to the position of dominance that it now occupies in the floras of the world.

A. C. SEWARD.

ELECTROSTATICS AND MAGNETISM.

A Text-book of Physics. By Prof. J. H. Poynting and Sir J. J. Thomson. *Electricity and Magnetism.* Parts i. and ii. *Static Electricity and Magnetism.* Pp. xiv + 345. (London: Charles Griffin and Co., Ltd., 1914.) Price 10s. 6d.

THE late Prof. Poynting's qualities as a physicist are reflected in the volume on electrostatics and magnetism now before us, for he was always distinguished by soundness and clearness of thought, and care and accuracy of experiment rather than by showy brilliance. The book is very clearly written, and evidently no trouble was spared in the attempt to make it as easily understood as possible. A large part of it is, in fact, a model of exposition, and could scarcely be improved upon. The chief value of the book, however, lies in the fact that it goes a little farther than the ordinary elementary text-book has done up to the present. Most English text-books deal in a very cursory way with both electrostatics and magnetism, and it is extremely useful to have a book which gives a somewhat more adequate treatment without at the same time becoming too difficult and exhaustive.

The chapters on "The Dielectric," "Specific Inductive Capacity," "Stresses in the Dielectric," "Alterations in the Dielectric," and "Pyro-electricity and Piezo-electricity," are particularly good in the "Electrostatics"; and those on "Forces on Magnetised Bodies," "Paramagnetic and Diamagnetic Substances," and "Magnetism and Light" in the "Magnetism." The simple statement of the titles of these chapters will give a clue to the difference between this text-book and others. All the extra matter is quite important, and in no way abstruse, yet a considerable part of it is not to be found in any other English elementary text-book. The great value of the book to students is therefore obvious, and is scarcely lessened by the few defects which exist.

The first and most serious of the faults of the book is the inconsistency with which previous knowledge in the student is assumed. The first chapters in both the electrostatics and the magnetism are written as if for students with absolutely no previous knowledge of the subjects, while to understand the chapters on magnetic induction a student would require a reasonable knowledge of the magnetic field due to a current. In a book of this character it would seem that the most reasonable assumption to make is that the knowledge of the student is of about the intermediate science standard. The extremely elementary general accounts of the common phenomena could thus be omitted, and one could start without any preamble on the more important part of the book.

The order in which the various divisions of the subject are taken is rather strange in places. It seems the reversal of the proper order to give a number of the consequences of an inverse square law of force in one chapter and to give the experimental proof of the law in the following chapter, but the most flagrant case is the attempt to give a general account of susceptibility, permeability, and the hysteresis loop before any of the magnetic quantities have been defined. To an elementary student these things would be very confusing, but as there is no doubt that all students who come to this book will bring with them a fair working knowledge of the most elementary parts of the subject, very little harm will be done.

A few not unimportant matters of detail might also be improved. There are two totally different definitions of quantity of electricity, one on p. 29 and one on p. 67. It is true that these two are consistent with one another, but this is not proved, and the first definition is quite unnecessary and is nowhere used. The definition on p. 42 of the electric potential at a point as $\frac{\Sigma Q}{r}$ seems to be converting potential into a mathematical symbol with no direct physical meaning. If we define the difference of potential between two points as V when the work done in taking an indefinitely small quantity dq from one point to the other is $V.dq$, we not only have the physical conception of work per unit quantity but we can also define any other kind of potential in an exactly similar way.

It is also desirable that Franklin's jar with its movable coatings should be given a long-deserved rest. It does not prove, what it was originally supposed to prove, that the seat of electrical action is in the dielectric; it merely proves that glass is a very bad substance to use as an insulator, because it so readily forms a conducting layer on its surface by the absorption of moisture from the atmosphere. A Franklin's jar made with a good insulator does not work, and therefore there seem to be no reasons for introducing it.

Most of the diagrams are very clear and suitable; they are of good size and are simplified as much as possible. But Fig. 194 on p. 250 offends the eye of a physicist just as keenly as a note badly out of tune offends the ear of a musician. One scarcely expects all the diagrams of lines of force and equipotential surfaces to be drawn accurately to scale, but one does demand that lines of force and equipotential surfaces shall not be palpably inclined to one another as they are

in this diagram. This certainly should be altered before a new edition is printed.

Although it takes a good deal of space to point out these defects, they are not numerous or important enough to decrease the value of the book sensibly. It is scarcely necessary to advise students to get the volume, as they will find it indispensable if they wish to obtain a good working knowledge of the fundamentals of electrostatics and magnetism.

(5) *The English Year: Spring*. By W. B. Thomas and A. K. Collett. Pp. ix+334+plates. (London and Edinburgh: T. C. and E. C. Jack, n.d.) Price 10*s*. 6*d*. net.

(6) *My Garden in Spring*. By E. A. Bowles. Pp. xx+308+plates. (London and Edinburgh: T. C. and E. C. Jack, 1914.) Price 5*s*. net.

(1) THE authors of this excellent elementary text are practised hands in the production of books on botany for students, and the present work is mainly a condensation of their larger work published a few years ago, entitled "Practical Botany," though from the abbreviated list of their works on the title-page one might infer that *each* author had published an earlier book with this name. However, it differs considerably in style from the authors' previous works, and indeed from most other elementary books on botany, in two features which are consistently kept in view throughout—namely, the emphasis which is laid on the dynamic side of botany, the plant being regarded as an organism forced to maintain its existence under conditions sometimes favourable and sometimes unfavourable to it, and the constant reference to the practical side of plant life in all its bearings. That is, while the work gives a good general grounding in botany, the ecological and the economic aspects of the subject, taken in the widest sense, are never lost sight of and at the same time are not unduly stressed. Since there are comparatively few references to plants unknown in the wild state or unfamiliar in cultivation in Britain, the book is one that can be warmly commended to teachers, at any rate to those who have no set syllabus to work from, while those responsible for the framing of syllabuses in elementary botany might learn much from a book like this as to what is wanted in the case of a subject with such marked educational significance. The book is generously illustrated, and the figures are remarkably clear and well executed.

(2) The Norfolk and Norwich Naturalists' Society is to be congratulated on the production of this admirable flora of a remarkably interesting county, a book which was certainly required, considering that the only previously published Flora appeared so far back as 1866 and has long been out of print. The editor of this work has left no stone unturned in his efforts to make the lists of the flowering plants and the higher flowerless plants of Norfolk as complete as possible, while he has enlisted the services of other writers in the earlier part of the book, dealing with climate, soils, physiography, and plant distribution, which precedes the plant lists. Both sections of the book are, however, open to a certain amount of criticism. While the articles on climate and on soils are all that could be desired, being admirably clear though brief, that on physiography and plant distribution is rather weak as regards the latter or vegetational aspect, though the part dealing with physiography is good so far as it goes. The author of what ought to be the most important portion of the general discussion of the flora of a county or other area fails to arrange his subject-matter clearly and logically, and his treatment of the ecology and distribution of the flora will, we fear, be useful neither to the average field botanist unfamiliar with the terminology or the ideas of modern ecological plant-geography, nor to the ecologist desiring to compare the vegetation of Norfolk with that of other parts of the country which have been systematically investigated from this point of view. In a flora of this kind, the general account of the vegetation should be preceded by an outline of general ecological principles, with an indication of the relations of the plant-communities represented in the area to the general scheme upon which these communities are based and classified. Again, in the systematic portion of the work, following on the flowering plants, we find the heading "Cryptogamia," but the list of flowerless plants stops short with the mosses and liverworts; either such a heading

should not be used, or the entire flora, including the lower cryptogams, should be dealt with.

(3, 4) Like the previous volumes with photographs in colour of British wild flowering-plants by Mr. Corke, and descriptions by Mr. Nuttall, these two series are extremely attractive books, though the text is, as before, less arresting than the plates, most of the latter being remarkably fine. The work is, however, intended for popular reading, and that it serves a useful purpose is shown by the mere fact that seven volumes, dealing with upwards of two hundred species, have now been issued. The number of the volume is indicated in each case by the curious device of a constellation of asterisks below the authors' names on the outside cover, but surely ordinary type would have been better than this. It is to be hoped that the authors will, in the further volumes of this series, include various flowering plants which, though devoid of conspicuous flowers and therefore less suitable perhaps for colour photographs, are of interest in other ways, as showing special adaptations of the vegetative organs for life in special habitats; if a few such plants were treated in each volume, the value of the latter for the drawing-room table would not be appreciably lessened, while their usefulness in other ways would be enhanced.

(5) The general get-up of this book, the post-impressionist style of a considerable proportion of text and coloured illustrations alike, and the extraordinary badness of the black-and-white figures, all combine to produce a loose, untidy effect which is evidently intentional, and intended for something very fine and striking, which somehow misses fire. The text is often sprightly and readable for a while, than one comes across pages of rhapsody and rubbish; sometimes we get really good observations and new points of view, but soon we are back to loose writing and absurd mistakes in the most elementary facts of plant and animal life. The book consists of a series of essays on a variety of topics more or less relating to the phenomena of springtime, and most of them give the impression of having been expanded, often by the interpolation of long bits of poetry, from articles written for the newspaper Press and kept within bounds by the exigencies of space in their original form. Much of the text is slovenly, will not bear parsing, to say nothing of scientific criticism; but probably it is only through careless proof-reading that the authors, after asking what are the most hackneyed lines on springtime, proceed to quote "Browning's 'O to be England,'" adding that "the lines are trite"—but any lines can be made less so when suitably treated.

(6) Here again the subject is spring, but with a difference. Mr. Bowles writes as one having authority on all gardening matters, and here he is perhaps at his best. He takes us through the kaleidoscopic pageant of spring in his garden, acting as guide, philosopher, and friend, dropping casually many valuable hints for those of his readers who would aspire to possess a garden with even a tithe of the rich collection he has brought together in his, and relating some amusing stories on the way. One of his chapter titles is somewhat startling—"The Lunatic Asylum"—and made us apprehensive of another excursion into very wild life, but after all it was only a piece of wild garden and the many and varied plants that were allowed to riot in it, so by way of "Tom Tiddler's Ground" we are brought back again into the Iris Walk, the Rock Garden, and so, with regret, to "The Culmination of Spring" and the end of a thoroughly delightful conducted tour.

OUR BOOKSHELF.

Marine Engineering (a Text-book). By Engineer-Captain A. E. Tompkins. Fourth edition, revised and partly rewritten. Pp. viii+812. (London: Macmillan and Co., Ltd., 1914.) Price 15s. net.

DURING the six years which have elapsed since the publication of the third edition of this book, marine engineering has made great progress, and the author has taken the opportunity of bringing the present edition up to date. Thus we find new matter giving account of recent turbine practice, including the power transmission and speed-reduction devices of Parsons, Föttinger, and others. The sections dealing with the internal combustion engine are now fairly representative of modern practice, and contain descriptions of both two-stroke and four-stroke Diesel engines. A great deal of attention has been given to condenser plants during the past few years, and the author has not overlooked the work and experiments of Mr. D. B. Morison, Dr. Weighton, and Messrs. Weir. The section on the use of liquid fuel in boiler furnaces is also very complete.

The book is intended primarily for sea-going engineers, and there must be very many such who can bear testimony to the value of the previous editions, and who will welcome the book in its present form. The descriptions and drawings are exceptional for their clearness, and while the calculations given are of the simplest character, sufficient of the theory is stated in all cases to enable the engineer to have an intelligent understanding of the machinery under his charge. The sections dealing with care and management of boilers and machinery, and with the duties of the engineer of the watch, are very useful, and will be of service to other than marine engineers.

The Examination and Thermal Value of Fuel: Gaseous, Liquid, and Solid. By J. H. Coste and E. R. Andrews. Pp. xvi+278. (London: C. Griffin and Co., Ltd., 1914.) Price 6*s.* net.

The importance of the scientific examination of fuels and the avoidance of wasteful methods of utilisation is becoming more and more recognised as it is realised that economy, both individual and national, must be exercised in their application. This small treatise deals with the methods of sampling, analysis, and determination of the calorific value of fuels of all classes, and the examination of flue gases.

The book will prove of considerable service in the laboratory, but it must be confessed that in some sections it is lacking in that personal assistance, the result of experience, one is led to hope for in the preface.

In gas analysis, for example, many are the pitfalls besetting explosion analysis, but beyond the usual outline of procedure, little help is given in avoiding the difficulties. Again, whilst the Petroleum Act regulations for testing the flashing point of burning oil (which is of minor importance as a fuel) are quoted *in extenso*, the flash point of heavier oils (those of special importance as fuel oils) is dismissed with the briefest description of the Pensky-Martens apparatus, and no description of the method of working is given or reference made to the precautions necessary to obtain good results.

The sections on calorimetry are undoubtedly the most satisfactory portions of the book, with much evidence of personal experience. Very ample consideration is given to questions affecting the accuracy of the results and the comparative value of different types of calorimeters. Now that purchase on calorific value is becoming more general and legal standards of calorific value of gaseous fuels already established, the whole subject of calorimetry has become of primary importance, and this book is certainly a useful addition to the literature on the subject.

Rapid Methods for the Chemical Analysis of Special Steels, Steel-making Alloys, and Graphite. By C. M. Johnson. Second edition, rewritten. Pp. xi+437. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 12*s.* 6*d.* net.

The first appearance of this book dates back to 1908, and the edition now brought out contains quite twice as much material as its predecessor. The chapters have increased from sixteen to twenty-one, whilst the subdivisions of chapters, which were so strange in the first edition, are still further elaborated. The new chapters deal principally with the analysis of ores, refractory materials (acid and basic), fluorspar, lubricating oils, and coal; whilst uranium, cobalt and nitrogen are added to the section on steels. Besides these the chapter on the determination of carbon is amplified considerably, and an interesting account of the estimation of oxygen in tungsten powders and in steels has been inserted. The valuation of nickel chrome steels and Monel metal have been given chapters to themselves. Unfortunately, the new portions (which deal practically entirely with the author's own work—the general literature being rather neglected) have been inserted in such a way as to give the book a very patched appearance. The arrangement has also resulted in several rather tiring duplications. A blue pencil wielded by a friendly though very free hand would have tended to a much improved book. In a work of this nature one naturally looks for all things up to date, and in consequence one is surprised to find no appreciation of the "reductor methods" that are so extremely useful in analysis of this kind. Among many other omissions may be mentioned the work of Gooch and his pupils on vanadium, molybdenum, etc., the recognised volumetric methods for manganese in ferro-manganese, the ignition of Brünck's precipitate to nickel oxide, and the iodometric estimation of copper.

Leslie Aitchison.

The Latest Light on Bible Lands. By P. S. P. Handcock. Second edition, revised. Pp. xii+371. (London: S.P.C.K., 1914.) Price 6*s.* net.

Archæology is a two-edged sword for those who would "prove the Bible," an uncertain lamp which may unexpectedly throw a distressing light on the mental calibre of chosen races; nay, more, traditions of similarities in Flood-narratives, or divergences in Creation-stories, may not unnaturally set up doubts in credulous minds as oppositions of science falsely so-called. It was one of the discoveries of Macalister at Gezer that Philistinism was a misnomer for boorishness, for the Philistines by the traces of their culture and civilisation there discovered have proved themselves to be far more worthy artists than the Hebrews. Mr. Handcock's book is of a kind which is published from time to time, giving the latest discoveries so far as they are analogous to the Old Testament, and recapitulating what was hitherto known. Here is again the Babylonian account of the Flood and the Creation of Man by Marduk from his own blood (why is no reference made to Mr. King, who first published the tablet containing the latter story?); an account of the Gilgamish epic and the Flood-story, told sufficiently accurately in their main points, although the distinction which the author makes in the epilogue is too nice for us ("'the gods came down to smell the sacrifice like flies,' a description which in its materialism contrasts somewhat strikingly with the dignified words of the Biblical writer, 'And the Lord smelled a sweet savour.'"); and a proper rejection of the Chedorlaomer theory. The chapters on the latest diggings in Palestine form a useful *précis* of what has been published by excavators, and Mr. Handcock gives also a full index of Old Testament place-names. In judicious hands his book will go far to provide a guard against one edge of the sword; it has been the writer's endeavour to allow the facts to speak for themselves.

R. C. T.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Age of a Herring.

THE very remarkable conclusions which Dr. Johan Hjort has drawn from his study of the scales of herrings are discussed, over well-known initials, in NATURE of August 27. Your contributor is evidently convinced of the truth of Dr. Hjort's deductions, and this opinion is shared, I believe, by very nearly all those biologists who make a study of fishery questions. Nevertheless, even in face of this general consensus of opinion, I am unable to persuade myself (on the evidence at present in hand) of the validity of Dr. Hjort's conclusions. The leading statements made by Dr. Hjort and his friends are these:—(1) That the age of each individual herring, or the year in which it was born, is at once made known by the number of rings upon its scales; (2) that, *ipso facto*, the shoal can be at once analysed into its component "year-classes"; and (3) that herring spawned in 1904 (according to such evidence) were so prodigiously numerous that year after year they have seemed to dominate the Norwegian herring-catch, and have constituted from 77 per cent. to 54 per cent. of all the Norwegian "spring herring" during at least the five years from 1910 to 1914.

To attempt to deal in a few words with all Dr. Hjort's careful work and laborious arguments is, of course, out of the question; but let me try to say as shortly as possible why I find it hard to follow him.

The whole argument depends on the primary assumption that the age of each herring is marked upon its scales, year for year, ring for ring. This is still a hypothesis. That there is no little circumstantial evidence in its favour I readily admit; but it has never been proved, and is only acceptable so long as the deductions to which it directly leads are themselves intrinsically acceptable.

Now if we sample at random a shoal of herrings, and analyse them acording to their scale-rings into so-called "year-groups," we find that these numbers range themselves with great apparent regularity in a unimodal skew-curve: just as the same fish group themselves also, according to size, in a unimodal but more normal curve. Here is one of Dr. Hjort's own samples, reduced to percentages as he himself gives it:—

"Age-groups," or Number of Scale-rings, in a Sample of 635 Herrings from the Dogger Bank (1910).

Number of rings	2	3	4	5	6	7	8	9	10	11	12	13
Presumed year of birth	1908	1907	1906	1905	1904	1903	1902	1901	1900	1899	1898	1897
Per cent. number of fish	0·2	8·4	14·2	21·3	18·9	14·3	9·3	5·7	5·5	1·3	0·8	0·3

Now, to say the least of it, it seems to me statistically improbable that a dozen separate generations of herrings, spawned in as many years, should have entered into the formation of the composite shoal in these curiously and regularly graded proportions. On the other hand, were we to assume that these herrings were *all of the same age and origin*, then we should have at hand an easy explanation of the facts, viz. that just as the individual herrings vary in a normal fashion about a certain modal size, so do they also vary, in the number of their scale-rings, about a certain modal number.

The rings on an oyster-shell are not just the same things as the rings on a herring's scale, but yet the analogy is not very remote. Miss A. L. Massy has lately made a study of oyster-shells, using oysters *of known age* from the hatchery at Ardfry. I extract from her data the following table:—

Analysis of a Sample of 341 Three year-old Oysters, according to the Number of Shell-rings.

Number of rings ...	2	3	4	5	6	7
Number of oysters ...	16	169	94	48	12	2

That is to say, in the case of the oyster the number of shell-rings does not correspond to the years of the oyster's age, but, on the contrary, is subject to variation according to regular and simple law. And the variability of the shell-rings in a sample of oysters all of identical age is in a very close degree similar to that of the scale-rings in a sample of herring drawn from one and the same shoal. The simple and crucial question is, then, whether in a shoal of herrings the evidence tends to show that all the fish are of one and the same age, like Miss Massy's oysters, or whether the shoal is a mixture of many generations, as Dr. Hjort asserts.

When we come to Dr. Hjort's final deduction, we find it illustrated, as your contributor tells us, by the following table, showing the manner in which successive "year-groups" of herring are said to have combined to constitute the Norwegian adult herring population of 1914:—

Spring Herring, 1914 (2205 *Fish Examined*).

Age (or number of scale rings)	Presumed date of Birth	Per cent. No. of fish
4 years	1910	0·6
5 ,, ...	1909	3·3
6 ,, ...	1908	6·9
7 ,, ...	1907	5·2
8 ,, ...	1906	7·2
9 ,, ...	1905	13·9
10 ,, ...	1904	54·3
11 ,, ...	1903	5·0
12 ,, ...	1902	1·5
13 ,, ...	1901	1·2
14 ,, ...	1900	0·4
15 ,, ...	1899	0·5

If we accept part of what this table sets forth, we must accept the whole. If we believe that the adult herring population consisted, to the extent of 54 per cent. of its total numbers, of herrings born in 1904, we must also believe that the remaining 46 per cent. was constituted of some eleven other successive yearly broods, all so nicely graded as to their proportionate amounts that these latter form an all but smooth curve, rising up to and falling away from the modal group of ten-year-old fish. Any normal population, as of men, consists, of course, of individuals of all ages, less and less numerous the greater their age. If there be, as among herrings there well may be, large and irregular fluctuations in the annual birth-rate, then the descending age-curve of the population would be irregular, one or more particular ages becoming unduly prominent. But that is a totally different thing from the population-curve which Dr. Hjort presents to us. He tells us that the 1904 group was, and has remained, so predominantly abundant as to constitute for several successive years from one-half to more than three-fourths of the whole stock of adult herrings; not merely that that year-group was more abundant than any one of its immediate successors or predecessors, but that it outnumbered all its contemporaries,

both older and younger, put together; and that this continued year after year, though all the while the great herring fishery was mainly supplied by drafts upon that identical and unfailing brood. That there are fluctuations in the abundance of fish, herring and others, is well enough known; that there are good spawning years and bad, or good and bad years for the survival and growth of the young, is also certain. But an increase of birth-rate or a diminution of natural mortality such as would cause the race of ten-year-old herring to outnumber all the rest put together, from four years old to fifteen, is very hard indeed to imagine.

Here, as it seems to me, is a clear case of a biological problem, based upon statistics, surrounded by mathematical difficulties, where the biologist cannot possibly be sure of his ground until he has enlisted the help of the mathematical statistician.

D'ARCY W. THOMPSON.

The Red Flash.

THE interesting recent letter (NATURE, vol. xciii. p. 664) on the green flash leads me to send a brief note on a much rarer correlative phenomenon, also, of course, due to atmospheric dispersion, viz., the red flash.

Let there be a cloud low down, with a well-defined lower edge, separated from the actual horizon by an interval of clear sky. Then, at the lower edge of the cloud, just as the base of the setting sun reappears, or that of the rising sun disappears, the red flash may be seen.

I have observed the green flash, connected with the top of the sun, scores of times; but the red flash, connected with its base, only about thrice, as the conditions are obviously much less frequently fulfilled.

I venture to think that "flash" is a more suitable term than "ray," for the latter may lead people to suppose that a long streamer of light is to be expected. I last saw the red flash at Clapham (Yorkshire) on September 11, 1913, at 6.30 p.m. It was preceded by a green flash at the upper edge of the cloud.

It may be well to add that, even when all circumstances seem to be apparently favourable, no flash (either green or red) may be visible. My own experience, now a long one, is that failure is decidedly more frequent than success.

C. T. WHITMELL.

Invermay, Hyde Park, Leeds, September 6.

OPENINGS FOR BRITISH CHEMICAL MANUFACTURERS.

AS a result of the state of war between this country and Germany and Austria an unprecedented opportunity has arisen of making a firm endeavour to establish the manufacture of a very large number of chemicals which have hitherto been produced mostly abroad.

It is a mistake to think, as many people do, that most of these are patented articles; on the contrary, the vast majority are very well-known products in considerable demand, and these ought first to receive the attention of the English manufacturer.

It is very desirable, however, and no doubt this course is being largely pursued, that existing manufacturers should endeavour to extend their energies to the production of materials of a similar character to those which they already make, and not to enter an unknown field of manufacture unless they feel very sure of their ground. We have, in this country, the nucleus of a vast chemical industry embracing all, or very nearly all, the ramifications that have been so exhaustively extended by the large German chemical works, and now is the time for that nucleus to expand in a natural way until all our requirements and those of our colonies, our allies, and the neutral States can be fulfilled.

This is a point that requires insistence, as there is considerable danger of manufacturers rushing into the production of materials, hitherto bought from abroad, and only incidentally used in their own business, which in many cases have already been made here, or which, on application to the maker of allied substances, could be produced by him with a minimum expenditure of money and labour. Thus the soap-boiler who has formerly purchased foreign synthetic perfumes, the perfume maker who has bought aniline dyes, the aniline dye manufacturer who has had to depend on Germany for his raw materials, all should apply to existing English manufacturers of their requirements before embarking upon the production of materials foreign to their manufacturing experience. The writer has experienced several cases of manufacturers proposing to prepare chemicals which they imagine have been entirely made in Germany, who have been surprised when informed that such are produced in large quantities in this country.

At the same time, however, there is undoubtedly a great opportunity for starting new manufactures in various directions, but the products to be considered first should be of as simple a nature as possible, especially in the case of organic substances, for the successful manufacture of many of the more complicated of these can only, in most cases, be attained after several years' work.

As regards those articles which are patented or protected by a trade mark the Board of Trade has made rules (Patents, Designs, and Trade Marks (Temporary) Rules, August 21, 1914), under which a German or Austrian patent may be entirely suspended, so that there need be no difficulty in obtaining permission to manufacture according to such patents, and, indeed a large number of applications to this end have already been received at the Patent Office.

Further, it may be stated that, although various organic substances can only be made with the use of ethyl or methyl alcohol, methylated spirits not being suitable, the regulations with regard to these under the Finance Act of 1902 make it possible to use them in manufacture in a convenient manner, and it is for the would-be user to suggest to the Commissioners of Customs and Excise the means by which it is proposed to make the spirits unpotable. This object is obviously easily attained by using either the raw material or the finished product as the "denaturant."

Of the actual chemicals for which there is a demand now owing to the stoppage of imports from the continent, perhaps potassium salts take the first place, as the Stassfurt deposits have, for

a considerable time, been their chief sources. Other sources of potassium salts, however, exist in the nitre found in India and in the kelp of the West Highlands, and it seems feasible to suggest that the latter industry should be taken up again, as it furnishes not only potassium salts but also iodine (compare in this connection W. R. Scott, Report to the Board of Agriculture on the kelp industry in the West Highlands, Blue Book, Cd. 7564).

It must not be forgotten that in many cases sodium salts can be used instead of potassium; thus the bromide, chlorate, dichromate, and permanganate of sodium might be manufactured instead of the potassium salts. In this connection it may be as well to point out that there must be a large amount of potassium salts stored in the various universities and technical schools of this country which might be collected, and, where necessary, worked up for the supply of those salts which are needed now for medicinal purposes in hospitals, etc., until a further supply becomes available. The ordinary employment of potassium salts in the laboratory can easily be avoided by the use of sodium salts in almost every case.

An important industry is that of the manufacture of thorium nitrate, which is used so largely for incandescent mantles. Although this compound is already made in England, the supply is not equal to the demand, and there ought to be little difficulty in diverting the chief source, viz., monazite sand, from Brazil to this country.

The manufacture of the large amount of glass chemical apparatus and other articles, such as cylinders for incandescent lamps, hitherto made from the so-called "Jena-glass"—a borosilicate glass containing zinc and barium oxides—ought certainly to be taken up by English glass makers, and the Potteries should seriously consider the question of supplying Berlin porcelain.

Turning now to the organic side of chemical industry there is a very considerable demand for formic acid and formaldehyde and its derivatives used in medicine, such as hexamethylenetetramine (urotropine), but of all organic medicinal drugs perhaps the greatest shortage is in salicylic acid, which is required also in the preparation of certain dyestuffs. Hitherto the world's supply has been provided by a large German works, and the manufacture of such an important substance in this country is very necessary. Provided with this the production of such drugs as salol (the phenyl ester) and aspirin (the acetyl derivatives) is rendered possible. Other acids, such as benzoic, citric, and tartaric, are also needed.

Of other well-known drugs the manufacture of acetanilide and phenolphthalein is easy, whilst that of phenacetin (acetyl-*p*-phenetidine), atophan (2-quinoline-4-carboxylic acid), antipyrine (phenazone), and its various derivatives, sulphonal and its congeners, veronal, the various guaiacol compounds, and the organic arsenic derivatives, such as atoxyl and salvarsan, is more difficult.

Closely allied to many of the above, from the manufacturing point of view, is the large class of photographic developers, amongst which may be mentioned pyrogallol, hydroquinone, and metol (methyl-*p*-aminophenol sulphate), and synthetic perfumes, such as vanillin, artificial musk, ionone, heliotropine, etc.

Efforts will no doubt be made to produce in England the great quantity of organic dyestuffs hitherto imported from Germany. A considerable number has also been provided by Switzerland, and presumably this importation will continue. A large amount of azo-, nitro-, alizarin, and sulphur dyes has been produced for a long time in England, as well as indulines, magenta, aniline blues, methylene blue, etc., and no doubt the manufacture of these is being largely increased, but there is a great field open to the British manufacturer in the case of vat dyes, such as indanthrene, and its derivatives, of which the raw material is already made here, and synthetic indigo and its derivatives, including thioindigo.

J. C. CAIN.

NOTES.

WE regret to see the announcement of the death, at sixty-six years of age, of Dr. W. H. Gaskell, F.R.S., University lecturer in physiology, Cambridge.

THE *Morning Post* announces that the Huxley Memorial Lecture at Charing Cross Hospital on recent advances in science and their bearing on medicine and surgery, by Sir Ronald Ross, originally fixed for October 1, has been postponed to Monday, November 2.

THE death is announced of Mr. H. M. Freear, chemical assistant at the Woburn Experimental Farm and Pot-culture Station of the Royal Agricultural Society, and a leading authority upon the relation of pot-culture experiments to practical agriculture and horticulture.

MR. EDWARD RILEY, whose death is announced, at eighty-three years of age, was early associated with the production of Bessemer steel at the Dowlais Iron Works in South Wales, where he was chemist from 1853 to 1859. At the May meeting of the Iron and Steel Institute this year, he was awarded the Bessemer gold medal in recognition of his work in analytical chemistry and metallurgy.

AN announcement was made in NATURE of June 18 (p. 415) to the effect that Mr. Thomas Cawthron, of Nelson, New Zealand, had made a gift of 50,000*l.* for a beginning for a solar observatory to be erected in New Zealand. Miss Mary Proctor asks us to state that the amount is "30,000*l.* for a beginning," and that she is responsible for the conflicting statements which have been made, as she was "under the mistaken impression that the amount was 50,000*l.*, and made a statement to that effect without being duly authorised."

THE death is announced, on September 8, at seventy-four years of age, of Mr. William Erasmus Darwin, eldest son of Charles Darwin. It was with reference to this son that Darwin wrote in his autobiography:—"My first child was born on December 27, 1839, and

I at once commenced to make notes on the first dawn of the various expressions which he exhibited, for I felt convinced, even at this early period, that the most complex and fine shades of expression must all have had a gradual and natural origin." These notes provided a natural explanation of phenomena which appeared to be a difficulty in the way of the acceptance of organic evolution, and they formed the basis of the volume, "Expression of the Emotions in Man and Animals," published in 1872.

FROM Göttingen the news is announced of the death of Prof. Wilhelm Lexis, the economist, whose name is well known to students in connection with the "Handwörterbuch der Staatswissenschaften." Lexis was born on July 17, 1837; matriculated at Bonn in 1855, reading there mathematics and natural science. After graduating he was an assistant master at Bonn until 1861, when he went to Paris to study French economic conditions. Very soon he became known as an authority on economic problems, and in 1872 he was appointed to the chair of political economy at Strassburg. Two years later he was called to Dorpat; thence in 1876 he went to Freiburg, where he remained eight years. In 1884 he moved to Breslau, and in 1887 to Göttingen. Here he taught economics for twenty-five years, retiring in 1912 with a reputation that was world-wide.

SINCE the discovery of well-preserved skeletons of ancestral horses in the Eocene formations of North America, palæontologists have been anxious to compare the skulls of these specimens with one from the London Clay of Harwich, which was described by Owen in 1858 under the name of *Pliolophus vulpiceps*. This fossil, in association with various limb-bones of the same animal, was obtained by the Vicar of Harwich at that time, the Rev. Richard Bull, who gave portions of the upper and lower jaws and some fragments of limb-bones to the British Museum, but retained the greater part of the specimen. Since then it has been lost to science, but it now appears that all the associated remains have been carefully preserved by the widow of the discoverer exactly as he left them, and they have just been presented by Mrs. Richard Bull to the Geological Department of the British Museum (Natural History). The skull of Pliolophus, which still remains unique, is thus again accessible for study and comparison. As pointed out by Mr. R. Lydekker, it is probably referable to a species of Hyracotherium.

THE Smithsonian Institution has issued a treatise on atmospheric air and its relation to tuberculosis, by Dr. Guy Hinsdale, one of the prize essays presented in connection with the Washington Tuberculosis Congress (Publication No. 2254, Smithsonian Miscellaneous Collections). The author does not claim that there is any specific climate for tuberculosis. Of first importance are chemically and bacteriologically pure air and sunshine. One thing to be avoided is a climate in which the humidity varies greatly. Probably the best combination is a low humidity and a moderately cool temperature.

THE Local Government Board has issued a supplement containing a third report on infant mortality dealing with infant mortality in Lancashire, by the medical officer of the Board (Dr. Newsholme), and Drs. Copeman, Manby, Farrar, and Lane-Claypon. This county contains nearly one-seventh of the total population of England and Wales, and it suffers from a rate of infant mortality which is equalled in few other parts of the country. The evidence suggests that the most important factors conducing to this are (1) the continuance of unsatisfactory methods of dealing with excremental and domestic refuse; (2) unsatisfactory conditions of housing; (3) the industrial employment of married women during pregnancy and confinement; (4) a relatively low standard of life, especially among the miners.

To the current number of the *Psychological Review* Mr. W. S. Hunter contributes a paper on the after-effects of seen movement, in which several new observations are recorded. He finds that if the original movement be observed by one eye, and if a stationary surface be afterwards viewed by the resting eye, a faint, but distinct, after-movement is noticeable. This after-effect, however, occurs only when the moving field first regarded consists of parallel lines; it does not occur in the case of a rotating spiral. The writer attributes the illusion in the resting eye to eye-muscle strains arising from inhibition of the reflex tendency to follow moving lines; in conformity with which view he finds that in the case of parallel lines the after-effects are reduced or abolished when the eyes adopt a position of strain. He also notes that the illusion can, in part, be successfully controlled by the subject, and hence concludes that in the case of parallel lines the after-movement is determined by "associative factors" and eye-strain, in addition to the retinal changes which, in the case of the rotating spiral, alone play an important part.

IN the Journal of the Gypsy Lore Society (vol. vii., part iii.) the latest theory of the Indian origin of the Gypsies, that of Prof. A. C. Woolner, is discussed. He arrives at the conclusion that the theory of their origin from the Jats is unsupported by philology, and is opposed by the fundamental differences between the characters of the typical Gypsy and the typical Jat. Their connection with the Kafirs of the Hindu Kush is equally improbable. The physique of the modern Dom is very different from that of the present Gypsy, but both types may have been modified by environment and by intermixture with other tribes. Something is to be said for the view of Mr. H. L. Williams (Journal Gypsy Lore Society, vol. v.), who connects them with the Sansiyas and other criminal nomads of Northern India. On the whole, Prof. Woolner's view that the Indian element in Romani is not homogeneous, and that when this type of speech left Indian soil it already contained elements picked up in different parts of that area. In other words, the Gypsies were originally wanderers, and then, as now, picked up in their wanderings unconsidered trifles in the shape of words and grammatical forms. This seems to be a reasonable view, and the evidence appears to point to a migration of the nucleus of the

race from south-east India to the north-west, whence they passed westward from the neighbourhood of Peshawar.

The seventh annual report of the American Bison Society contains two very satisfactory items—first, that the number of pure-bred bison living in the country at the end of 1913 (inclusive of the 549 calves born the same year) was no fewer than 3788, and, secondly, that the society has decided to include within the scope of its aims the protection of the prongbuck, a species now standing in urgent need of such assistance. It should be added that there is a discrepancy in regard to the number of living bison in different parts of the report, the number given in the president's address being 3453, and that in the summary by the secretary the figure quoted above.

The imperfections of our seismic records are most noticeable during the periods of great European wars. Accounts of recent earthquakes are, of necessity, rare or brief at the present time; but, in neutral countries, seismological inquiries are being carried on as usual. The weekly bulletins of the Hawaiian volcanic observatory, for instance, record the changes that occur from day to day in its neighbourhood. In the last number (No. 27) Mr. H. O. Wood reports on the earthquakes registered in the Whitney Laboratory of Seismology at Halemaumau from April 21 to July 22, 1914. During these three months sixty-one local shocks were registered, of which only five were perceptible without instrumental aid. The number of shocks is thus at present small for a volcanic centre, but a considerable increase in their frequency will no doubt herald any important outburst.

The earthquakes of Norway have recently been studied in detail by Mr. C. F. Kolderup (Bergens Museums Aarbok, 1913, pp. 1–152). He gives first a list of the more important earthquakes from 1612 to 1886. After the latter year, the chronicle becomes much more complete. During the twenty-five years 1887–1911, the number recorded is 494, that is, at the rate of nearly twenty a year. In Great Britain the average annual number of earthquakes is twelve; so that, taking area into account, the frequency of earthquakes in the two countries is the same. The Norwegian earthquakes appear, however, to be of greater strength, six having disturbed areas of more than 50,000 square miles, the corresponding number for Great Britain being three. Again, the strongest Norwegian earthquake (that of October 23, 1904) disturbed an area of 367,000 square miles; while the strongest British earthquake (that of December 17, 1896) disturbed 98,000 square miles. In both countries the earthquakes are most frequent during the winter months; and, throughout the day, are most perceptible during the hours 10–11 p.m. and 1–2 a.m.

The limited literature on iridium in its mineral forms is enriched by Bulletin 17 of the Geological Survey of Tasmania (John Vail, Hobart, 1914), by W. H. Twelvetrees, on "The Bald Hill Osmiridium Field." The mineral occurs here as granules, with magnetite, chromite, nickeliferous pyrrhotine, and gold, in an altered peridotite, and is mostly won from alluvium. From the interesting review of the occurrence and use of iridium in the world at large, we gather that a certain mystery overhangs the trade, since the tipping of nibs for fountain-pens, and the production of hard ends for other apparatus, scarcely account for the increased demand for osmiridium.

Recent publications of the Geological Survey of the Department of Mines, Tasmania, are concerned with interesting mining areas. Bulletin 14, on "The Middlesex and Mount Claude Mining Field," and 15, on "The Stanley River Tin Field," describe the tin ores that were introduced into metamorphosed pre-Cambrian sediments by the uprise of granite in Devonian times. L. L. Waterhouse concludes that the banded ore-deposits of the Stanley River represent an actual replacement of the original country-rock, the structures of which are often preserved, even in the sulphide-ores. Bulletin 16, on "The Jukes-Darwin Mining Field," contains views of the forest-clad foothills and the great ridges of schist and granite east of Macquarie Harbour. The topography has been notably modified by glacial action.

The Australian Geological Surveys materially assist in the development of the resources of the country. Since the work that was noticed in Nature, vol. xciii., p. 307 (May 21, 1914), we have received several publications dealing with mineral deposits. E. C. Saint-Smith and R. A. Farquharson describe the Southern Cross area of the Yilgarn Goldfields (Geol. Surv. W. Australia, Bull. 49), where quartz-reefs occur in a complex country, which includes banded jaspers that may be of sedimentary origin. The most important reefs from an economic point of view occur as metasomatic replacements of schists along shear-zones, while those in the granite from which the siliceous infiltrations spread bear very little gold. The northern part of Kalgoorlie is described in Bulletin 51, and here the ferruginous jaspers, which have so wide an interest among the old rocks of both hemispheres, become in part graphitic as they approach deposits of sulphide ores.

It has been established by persistent statistical researches that the south-west monsoon rainfall in India is affected by various previous conditions in or outside that area, and seasonal forecasts based thereon have been made with more or less success since 1882. In a recent paper, entitled "A Further Study of Relationships with Indian Monsoon Rainfall" (Memoirs, vol. xxi., part viii.), Dr. Walker discusses at considerable length several correlations from all available data, but the results of this useful investigation have mostly proved to be of a negative character. (*a*) *Relationship with previous barometric pressure in India*: There is a tendency for the pressure of any year to be high when the monsoon is deficient, and *vice versâ*, but the indications do not seem to be of much practical use in forecasting the character of the monsoon a few months before its arrival. (*b*) *Relation with previous Indian temperature*: It is generally admitted that the monsoon rainfall is connected with the replacement of heated air by damper air from the ocean, and that years of high temperature in May should be years of good rainfall, but it is shown that this is not the case. Dr. Walker thinks that improved know-

ledge of conditions in the upper air will eventually throw light upon the matter. (*c*) *Effect of icebergs in the Southern Ocean*: From an examination of the Meteorological Office tables of icebergs published in the Monthly Meteorological Charts of the Indian Ocean, separately tabulated for each ocean, by Dr. Shaw's direction, it does not appear that the icebergs of the Indian Ocean have any material effect. The data for the South Atlantic appear to be more promising, but no definite conclusion can yet be formed.

THE Indian Association for the Cultivation of Science has republished, as Bulletin No. 10, under the title, "Optical Theories: a Brief Historical Survey," the address delivered by Prof. Mallik at the annual meeting in November last. In sixteen pages the author sketches the development of scientific ideas as to the nature of light from those of the early Greek philosophers to the modern view, according to which it is an electromagnetic phenomenon taking place in an æther through which are distributed singularities of a simple kind known as electrons and of a complex kind known as matter. He shows that at the time the Greeks were discussing the rival theories of Pythagoras, that light consisted of particles projected from luminous bodies to the eye, and of Empedocles, who held that for vision a so-called "visual influence" was necessary in addition, the Indian philosophers were discussing the problem on almost identical lines.

IN Mr. F. W. Lanchester's second article in *Engineering* for September 11, on aircraft in warfare, it is stated that the weaknesses of the dirigible on the defensive are so great and of such a character as to render it quite unfit to remain an active participant in aerial warfare. It may escape for a time, and may render a certain amount of useful service, but only thanks to the circumstance that the number of high-powered, fast-climbing aeroplanes is comparatively limited, and to the fact that scientific methods of attack have not yet been fully worked out or put into practice. However, even to-day the finest of Germany's fleet of Zeppelins would be absolutely at the mercy of a modern aeroplane in the hands of a man prepared to make his one and last sacrifice. So fragile and combustible a contrivance as a dirigible, whether rigid or non-rigid, can never, in Mr. Lanchester's opinion, survive in the face of the rapid development of the modern aeroplane and the engines of offence with which before long it will be furnished.

SOME interesting notes on the relation of rainfall and yield are contributed by Mr. D. Halton Thomson to *Engineering* for September 4. If the annual yield for a given drainage area be plotted against the rainfall for the corresponding period, the points generally are distributed in a haphazard manner, and there is difficulty in drawing a simple curve—usually assumed to be a straight line. The irregularities may be due to inaccurate observations, the varying physical conditions of the drainage area from year to year, and to the fact that the yield lags behind the rainfall. If twenty or more consecutive annual observations are available, the author suggests that the two phenomena may be correlated on the assumption that the rainfall of a given frequency produces a yield of the same frequency. Time-lag and difference of time-distribution may be eliminated by this means. The author derives a formula on this assumption for the Redmires drainage area of the Sheffield Waterworks, and finds $Y=R-14$, Y being the annual yield and R the annual rainfall, both in inches. The formula for the Trenchford drainage area of the Torquay Waterworks is $Y=0{\cdot}9R-13$. In the first case the annual evaporation is 14 in., whatever the rainfall, and in the second case the annual evaporation increases slightly with the rainfall.

THE *Engineer* for September 4 has an article dealing with the problem of pitwood supplies, the dearth of which, brought about by the war, is becoming a matter for serious consideration by colliery companies. Northern Russia, whence important cargoes have been usually shipped, is no longer able to keep up the supply, and scarcity of labour in south-west France has resulted in the suspension of cutting and transporting; shipments from Norway and Sweden are at present impracticable. It seems that only one alternative is to be found if the dearth of pitwood becomes extreme. To most collieries the permanent use of steel would be too expensive. It has been suggested that scrap tubes and rails, cut to suitable lengths, would make good substitutes for pit timber. A midland colliery has used for some time props made from old steel pipes; these are filled with soft and hard wood, the pipes forming a strengthener to the wood portion. This composite prop is lighter and stronger than the ordinary wood prop, is adjustable in length, and by its soft ends gives good warning of a collapse. Our contemporary suggests that the filling in of worked out parts of mines with sand, ash, slag, etc., would lead, among other important advantages, to a diminished demand for timber for pit purposes.

OUR ASTRONOMICAL COLUMN.

COMET 1913*f* (DELAVAN).—Delavan's comet is gradually moving westward among the stars; while it is now best observed in the early morning, it will, towards the end of the month, be an evening object for observation as well. The ephemeris given in this column last week is quite sufficient for anyone to detect this naked-eye object. Those possessing clock-driven equatorials can do useful work by strapping small cameras on to the telescope tube for the photography of the tail. During the evening of September 14 the comet was seen to have brightened very considerably, and was a conspicuous object to the naked eye. It was situated towards the west of θ Ursæ Majoris (3·2 mag.), but a more correct position would be to the west of 31 Ursæ Majoris, and close to this star. In fact, 31 Ursæ Majoris was involved in the tail. The nucleus closely approximated in brightness to ν Ursæ Majoris, a fourth magnitude star.

FURTHER NEWS OF ECLIPSE PARTIES.—The current number of the *Observatory* (September) publishes several items of interest about the parties which went out for the eclipse. It is stated that no news has come to hand about the Cambridge Solar Physics Observatory party, but that Mr. Stratton had been previously recalled for military service, and arrived in England on August 23. Major Hills and Prof. Fowler

describe briefly the attempt to reach their observing station at Kiev (Russia); they only got so far as Riga, and had to return. According to the *Morning Post* (September 7) the Russian astronomers were disappointed at the fact that Major Hills and Prof. Fowler when at Riga did not communicate with Prof. Backlund, because a Russian eclipse expedition went to Riga prepared to assist them in every way. As it happened, the weather at Riga was much finer than at most of the eclipse stations. The *Morning Post* gives further information about the German astronomers, who were invited to Russia to observe the eclipse. It seems that the German parties were warned in time to return, and some did so. Those who hesitated were arrested and sent to Odessa. It is then stated, "The American party packed up the German instruments and sent them also to Odessa, but nothing has been heard of them since, and the German astronomers have been vainly appealing to Prof. Backlund, who is naturally helpless and cannot interfere personally."

VERTICAL CIRCLE OBSERVATIONS AT THE U.S. NAVAL OBSERVATORY.—Vol. viii. (second series) of the Publication of the United States Naval Observatory contains the vertical circle observations made with the 5-in altazimuth instrument for the period 1898 to 1907. The observations were made by Messrs. F. B. Littell, G. A. Hill, and H. B. Evans, and were reduced by the first-named. The volume is subdivided into introduction, observations and reductions, individual results of observations and catalogue. The introduction contains an account of the instrument, which was built by Messrs. Warner and Swasey, under the supervision of Prof. William Harkness; it was completed and housed at the end of 1897, and first used in February, 1898. The aperture of the telescope is 5·02 in., and the focal length is 50 in. Two sections and a photograph of the instrument *in situ* illustrate the general arrangements. Pp. 1–389 show the observations and reductions; pp. 393–445 are devoted to the individual results of the observations; and pp. 447–65 give the catalogue. In the last-mentioned the magnitudes are those of the Revised Harvard Catalogue. The declinations are derived from the means of the individual results by the application of the corrections for flexure and latitude; they are for the epoch given in the column headed "Mean Date," and for the mean equator 1900·0. The precessions and secular variations are based on Newcomb's constants.

PARALLAXES OF THE BRIGHTER GALACTIC HELIUM STARS.—No. 82 of the Contributions from the Mount Wilson Solar Observatory, reprinted from the *Astrophysical Journal*, vol. xl., 1914, July, contains an extensive and important research by Prof. J. C. Kapteyn, entitled "On the individual parallaxes of the brighter galactic helium stars in the southern hemisphere together with considerations of the parallax of stars in general." The communication covers eighty-six pages, and is divided into twenty sections, the first being composed of an introduction and a summary. The stars chosen are the helium stars brighter than the 6th magnitude for the part of the sky lying between galactic latitudes ±30°, and galactic longitudes 216°–360°. In a subsequent paper or papers, he hopes to deal with the helium stars in the other parts of the sky. For the brighter stars of other spectral classes he has not attempted to derive individual parallaxes, but has discussed the prospects of the successful treatment of such an investigation. The reader must be referred to the paper itself for the details and results of the investigation, but attention may be directed here to the very interesting charts dealing with the distribution of the helium stars as regards galactic positions illustrating the apparent tendency of these stars to clustering. The most extensive of these clusters is between longitudes 200° and 340°, and this group forms the main subject of the present paper. Another chart gives the arrangement of the helium stars in space. Prof. Kapteyn directs particular attention to three fairly strong condensations with different parallaxes, and he says: "Of course, we may see in the arrangement of these condensations the indication of a spiral structure. I shall not lay much stress on this, unless we find the same thing repeated in other parts of the sky."

PAPERS ON INVERTEBRATES.

THE anatomy of the blind prawn of the Sea of Galilee (Lake of Tiberias), described by Dr. Calman in 1909 as the representative of a peculiar genus, under the name of *Typhlocaris galilea*, is discussed by Mr. Ghosh in vol. ix., No. 6, of the Journal and Proceedings of the Asiatic Society of Bengal. In another article in the same issue Messrs. Annandale and Kemp point out that, so far as known, the Sea of Galilee is the home of only three species of decapod crustaceans, of which the aforesaid Typhlocaris is noticeable on account of its marked structural differences from all other members of the group, as well as for its apparent modification for subterranean existence. As a matter of fact, it is known from a single open and well-lighted pool near the marge of the lake, and the authors suggest that earth-movements may have been the cause of this departure from its apparently proper habitat.

In the April number of the Records of the Indian Museum, Mr. Kemp continues his notes on the decapod crustaceans in the Indian Museum, dealing in this instance with the family Hippolytidæ, a group notable on account of the great generic variation in bodily form and in secondary sexual characters. Several species and two genera are described as new.

New and other African scorpions, spiders, etc., form the subject of an article by Mr. J. Hewitt in vol. iii., part 1, of Records of the Albany Museum. It is noteworthy that a two-lunged spider, *Cydrela friedlanderi*, of the family Zodariidæ, resembles the members of a totally different group in closing the entrance to its burrow by means of a trap-door. In the two-lunged trap-door species the females are bright-coloured like their allies, which do not protect themselves in the same manner; in other trap-door spiders, on the contrary, the females lack bright colours.

Two infusorians of the family Cothurnidæ found in moss during Dr. Charcot's Antarctic expedition led Mr. E. Penard to undertake a re-investigation of moss-dwelling rhizopods and infusorians, the first result of which is an elaborate article on the Cothurnidæ communicated by that naturalist to the *Mém. Soc. Phys. et Hist. Nat. Genève* (vol. xxxviii., fasc. 1). These organisms form an important feature of the invertebrate life of the polar regions, where moss and lichens constitute the chief vegetation; they are, however, by no means restricted to high latitudes, and the author has devoted much attention to the question whether in warmer zones they may not pass part of their time in open water. His answer is that while some are exclusively moss-dwellers, others appear to spend weeks, if not months, periodically in water.

Among the contents of the first *livraison* of vol. xlv. of *Trav. Soc. Imp. Nat., St. Pétersbourg.*, is an article on the anatomy and physiology of the synaptid holothurians, to which a brief abstract in French is appended.

We have been favoured with copies of three papers contributed by Mr. E. W. Adair to the *Bull. Soc. Entom. d'Egypte* for 1912 and 1913, published 1914. In the first (1912) of two relating to the life-histories of the insects of the family Mantidæ it is pointed out that the supposed additional metamorphic stage recorded by Pagenstecher in the case of *Mantis religiosa* was due to the newly emancipated imago being enveloped in the amnion of the ovum. In the third paper the author records "jumping seeds" of *Tamarix nilotica*, the movements of which were produced by imprisoned larvæ of a small weevil, *Nanophyes maculatus*. Hitherto similar movements have been known only in the case of the Mexican so-called "jumping beans," of which the moving power are the larvæ of certain tortricid moths, especially *Carposapsa saltitans*.

In an article contributed to vol. iv. (new series), part i., of the Transactions of the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne, Mr. R. S. Bagnall states that whereas a few years ago only a single representative of the centipedes of the group Symphyla was known from the British Isles, he had been enabled to raise the number to no fewer than twelve species and one subspecies, five of the former, of which three are described as new, belonging to the genus Scutigerella, and the remaining seven, of which six are new, together with the subspecies (also new) to Scolopendra. In a supplemental article published near the end of the same issue he describes a seventh new species of Scolopendra, from Cheshire, and raises the aforesaid subspecies to specific rank, thus recording a total of fourteen British species, of which, however, one Scutigerella has hitherto been detected only in hothouses.

In No. 1 of vol. v. of the Entomological Series of the Memoirs of the Department of Agriculture, Mr. C. C. Ghosh continues his life-histories of Indian insects, dealing in this instance with eleven species of butterflies, inclusive of the common British cabbage-white. The account of the rice-leaf caterpillar, and its butterfly, so injurious to rice-crops all over the Old World and Australia, is from MS. left by Mr. Maxwell-Lefroy, when Government entomologist. The nine coloured plates are admirably executed.

Fuller acquaintance with the insect-fauna of the eastern and north-eastern districts of the Transvaal and southern Rhodesia has enabled Dr. L. Péringuey to add considerably to the list of South African representatives of the hymenopterous family Mutillidæ. His first article on the subject was contributed to vol. i. of the *Annals of the S. African Museum* (1898): his latest forms part 15 of vol. x. of the same serial (1914).

Beetles of various families, inclusive of the Tenebrionidæ, Cetoniidæ, and Buprestidæ, collected during the Duke of Mecklenburg's travels, form the subject of articles by various specialists in Lief. 3 of the first volume of the Zoological section of *Ergebnisse der Zweiten-Deutschen Zentral-Afrika-Expedition*, 1910–1911. Many new species are named, and it may be well to note that the name of the Ubangi Valley has been adopted as a generic designation, "Ubangia."

An extensive collection of brittle-stars, or ophiurids, from the Caribbean Sea in the U.S. National Museum has enabled Prof. René Koeler not only to describe a number of new species, but, what is more important, to rectify the definition of previously known species and groups. His monograph, illustrated by eighteen beautifully executed plates in black and white, forms Bulletin No. 84 (173 4to pp.) of the U.S. National Museum. R. L.

OFFICIAL FISHERY PUBLICATIONS.[1]

IN its annual report for the year 1912, the fisheries branch of the Board of Agriculture and Fisheries made a marked change in the manner of reporting the results of their administration, and we are glad to note that this change is still more apparent in the report for last year. For the first time we are now presented with an account of the progress of the English sea fisheries, which is characterised by close insight into the conditions of the industry, and by a very attentive study of those tendencies that are making for the modification, in many ways, of the fisheries of England and Wales.

Part i. of the report is a document of great interest even to the ordinary reader interested in public affairs. It deals clearly and concisely with the industry in general, emphasising various matters of special importance arising during 1913. The remarkable herring fishery of the last two years; the great development, during this time, of the fishery for herring by means of the trawl net; the utilisation of by-products; the development of the internal combustion engine as a means of propulsion of fishing vessels; the application of wireless telegraphy in the deep-sea fisheries; the economics of the French sardine industry; the rapid development of scientific research by the Board: these and other matters, together with a good review of the year's fisheries and the administrative work of the Board, make up this interesting volume. Part ii. is a document for the specialist. It consists of statistical tables and synoptic charts, and those concerned with fisheries inquiries will welcome the increasing amount of detail exhibited in this representation of the year's fisheries. Still greater detail in relation to the less important fisheries is desirable, but it is apparent that, for this purpose, a much greater development of local administration by the Board may be necessary.

These reports are a contribution, though in a greatly modified and much more valuable form, of the former fisheries reports of the department. The third paper before us begins a new series of publications containing the results of scientific researches carried out by the officers of the Board. It is a statistical account of the English haddock fishery in the North Sea. The species is one which is most abundant in the northern parts of the North Sea, less abundant to the west of Great Britain, and practically absent, or capricious in its distribution and abundance, in the Irish Sea and the English Channel. Commercial statistics are utilised by Mr. Russell to give a picture of the distribution of the fish, and of its seasonal abundance, and the variations of abundance from year to year. These statistical summaries are most valuable; they indicate irresistibly those periodic fluctuations which are plainly to be correlated with periodic physical changes in the sea, or even with periodic cosmic changes. Measurements of length, of samples of fish taken at the great ports, are also summarised by Mr. Russell, and are so treated as to supplement the commercial statistics. In this way more than two and a half millions of fish have been dealt with. Biological observations have also been made, but a discussion of these is reserved for a future report.

Numerous determinations of average weight of the fishes landed are also summarised, with the object of throwing light on the variations in nutrition according to age and season. The author shows that the well-known length-weight formula now used in fishery

[1] Board of Agriculture and Fisheries. Annual Report on the Sea Fisheries for the Year 1913. Part i., Report; Part ii., Tables and Charts. [Cd. 7448–9] (1914.)
Fishery Investigations. Series ii., vol. i., part i., Report on Market Measurements in Relation to the English Haddock Fishery during the Years 1909–11. By E. S. Russell. (1914.)

investigations does not apply to his series. According to this formula, the weight of a fish at different ages is a function of the cube of the length. A mathematical investigation of Mr. Russell's average weights by Pearson's "method of moments" shows, however, that the weight of a fish at different ages is to be represented only by a series of the form,

$$a+bl+cl^2+dl^3+\ldots,$$

l being the length of the fishes. It is possible that these terms have each a physical meaning; the fish grows irregularly as its age advances, so that its weight is a function of length, surface, volume, and density, all of which dimensions vary in relation to each other in different phases of the individual life-history.

WATER SUPPLY.[1]

ONE of the difficulties besetting the agriculturist in the vast area known as the Great Plains and constituting the central region of the United States is the irregular rainfall. The land is fertile enough, but a recurring series of dry years militates greatly against its effective development. Attempts have been made to remedy the evil by means of artificial irrigation, but so far these efforts have been sporadic and local, and, consequently, they have not produced the completely beneficial results which might be obtained if all the ground water were systematically conserved and utilised.

The United States Government hydrological service, as the result of their investigations, are publishing from time to time a series of water supply papers specially devoted to a consideration of this problem as affecting various localities, and four reports before us (Nos. 345 A, B, C, and D), issued this year, deal with districts in Oklahoma, Kansas, and New Mexico. They are useful little pamphlets, affording much detailed information on the geological formation and available water resources of the respective areas. Not the least useful feature, perhaps, is a discussion on the depth and cost of wells, and on the power required for pumping. There is a much-needed caution to prospective irrigators to consider carefully the whole of the outlay likely to be involved in any system of artificial irrigation before embarking upon it, lest it should prove to be financially unremunerative and unsound.

Water Supply Paper, No. 340 A (Washington: Government Printing Office, 1914), of the United States Geological Survey, contains a list of the stream-gauging stations situated in the North Atlantic coast drainage basins, and a summary of the reports and publications relating to water resources within this area (1885–1913). It forms a convenient bibliographical index, and should prove most useful for reference purposes to anyone desirous of consulting the literature on the subject.

Three annual reports on the discharge of rivers in the United States are comprised in Water Supply Papers, Nos. 309, 322, and 324 (Washington: Government Printing Office). The first deals with the Colorado River Basin for the year 1911; the other two are for the year 1912, and cover the St. Lawrence River Basin and the basins of the South Atlantic coast and eastern Gulf of Mexico respectively. The numerous observations made have been carefully compiled and tabulated, and, in conjunction with those previously published, form a very useful scientific record of stream flow and discharge in the areas specified. Each pamphlet has an introductory note on the methods employed in gauging, and, in the 1912 reports, there are some interesting photographs and diagrams.

Paper 345 *c*: Underground Water of Luna County, New Mexico. Paper 345 *d*: Ground Water for Irrigation in the valley of North Fork of Canadian River, near Oklahoma City, Oklahoma, Washington, 1914. Government Printing Office.

THE AUSTRALIAN MEETING OF THE BRITISH ASSOCIATION.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY SIR EVERARD IM THURN, C.B., K.C.M.G., PRESIDENT OF THE SECTION.

A Study of Primitive Character.

CIVILISATION and "savagery"—for unfortunately it seems now too late to substitute any term of less misleading suggestion for that word "savagery"—are the labels which we civilised folk apply respectively to two forms of human culture apparently so unlike that it is hard to conceive that they had a common origin—our own culture and that other, the most primitive form of human culture, from which, at some unknown and distant period, our own diverged. But, assuming one common origin for the whole human race, we anthropologists can but assume that at an early stage in the history of that race some new idea was implanted in a part of these folk, that is, in the ancestors of civilised folk, which caused these thenceforth to advance continuously, doubtless by many again subsequently diverging and often intercrossing roads, some doubtless more rapidly than others, but all mainly towards that which is called civilisation, while those others, those whom we call "savages," were left behind at that first parting of the ways, to stumble blindly, advancing indeed after a fashion of their own, but comparatively slowly and in a quite different direction.

It is easy enough for civilised folk, when after age-long separation they again come across the "savages," to discern the existence of wide differences between the two, in physical and mental characteristics, and in arts and crafts; it is not so easy, it may even be that it is impossible, to detect the exact nature of these differences, especially in the matter of mental characters.

As a rule the occupant of this presidential chair is one who, whether he has seen much of "savages" at close quarters or not, has had much ampler opportunity than has fallen to my lot of comparative study of that great mass of anthropological observations which, gathered from almost every part of the world, has now been recorded at headquarters. I, on the other hand, happen to have spent the better part of my active life in two different parts of the world, remote from books and men of science, but in both of which folk of civilised and of savage culture have been more or less intermixed, but as yet very imperfectly combined, and in both of which I have been brought into rather unusually close and sympathetic contact with folk who, whatever veneer of civilisation may have been put upon them, are in the thoughts which lie at the back of their minds and in character still almost as when their ancestors were at the stage of savage culture.

While trying to adjust the mutual relations of wild folk and of folk of civilised stock, I have seen from close at hand the clash which is inevitable when the two meet—a clash which is naturally all the greater when the meeting is sudden. Moreover, having started with a strong taste for natural history, and

especially for the natural history of man, and having had much guidance from many anthropological friends and from books, I have perhaps been especially fortunate in opportunity for studying the more natural human animal at close quarters and in his natural surroundings. I have tried, from as abstract and unprejudiced a point of view as possible, to understand the character, the mental and moral attitude, of the natural "savage" as he must have been when civilised folk first found him and, at first without much effort to understand him, tried abruptly to impose an extremely different and alien form of culture on this almost new kind of man.

I venture to claim, though with diffidence, that I may have begun to discern more clearly, even though only a little more clearly than usual, what the primitive man, the natural "savage"—or, as he might more accurately be described, the wild man—was like; and it seemed possible that an attempt to bring together a picture—it can hardly be more than a sketch—of the mentality and character of some one group of people who had never passed out of the stage of "savagery" might be interesting and practically useful, especially if it proves possible to disentangle the more primitive ideas of such people from those which they subsequently absorbed by contact, at first with other wild, but less wild, folk, and later with civilised folk; and that a further study of the retention by these folk of some of their earlier habits of thought during later stages in their mental development might suggest a probable explanation of certain of their manners and customs for which it is otherwise hard to account.

The attainment of some such understanding is, or should be, one of the chief objectives of the practical anthropologist, not merely for academic purposes, but also for the practical guidance of those who in so many parts of our Empire are brought into daily contact with so-called "savages."

Perhaps hardly anywhere else in the world would it be possible to find better opportunity and more suitable conditions for such a study as I now propose than in the tropical islands of the South Seas. The ancestors of these islanders, while still in purely "savage" condition, must have drifted away from the rest of the human race, and entered into the utter seclusion of that largest of oceans, the Pacific, covering as it does more than a third of the surface of the globe, long before the first man of civilised race, Balboa, in 1513, from the Peak in Darien, set eyes on the edge of what he called "the Great South Sea," before Magellan, in 1520, forced his way into and across the same sea, which he called the Pacific, and certainly long before civilised men settled on any part of the shore of that ocean, *i.e.*, in 1788, at the foundation of Australia. For when first studied at close quarters by civilised folk from Europe, which was not until after the last-named event, these South Sea "savages" had been in seclusion during a period sufficiently long—and certainly no short period would have sufficed for such an effect—not only for them all to have assumed characters, cultural and even physical, sufficient to distinguish them from all other folk outside the Pacific, but also for them to have split up into many separate parties, probably sometimes of but few individuals, many of which had drifted to some isolated island or island-group, and had there in the course of time taken on further well-marked secondary differences.

It will probably now never be discovered when, how often, and from what different places the ancestors of these folk reached the Pacific. It is quite possible that they entered again and again, and were carried by winds and currents, some from west to east and some in the reverse direction, many perishing in that waste of waters, but some reaching land and finding shelter on some of that great cloud of small islands which lie scattered on both sides of the equator and nearly across that otherwise landless ocean.

Of the folk who in those old times thus drifted about and across the Pacific, the most important, for the part which they played in the story which I am endeavouring to tell, were the two hordes of "savages" now known respectively as Melanesians and Polynesians. Without entering deeply into the difficult subject of the earlier migrations of these two hordes, it will suffice here to note that, towards the end of the eighteenth century, when European folk at last began to frequent the South Sea Islands, and when consequently something definite began to be known in Europe about the islanders, certain Melanesians, who had probably long previously drifted down from north-westward, were found to be, and probably had long been, in occupation of the exceptionally remote and isolated Fiji Islands; also that, long after this Melanesian occupation of these islands, and only shortly before Europeans began to frequent them, several bodies of Polynesians, who had long been in occupation of the Friendly or Tongan islands, lying away to the east of Fiji, had already forced or were forcing their way into the Fijian islands.

The meeting in Fiji of these two folk, both still in a state of "savagery," but the Polynesians much further advanced in culture than the Melanesians, at a time before European influence had begun to strengthen in those islands, affords an exceptionally good opportunity for the study of successive stages in the development of primitive character, especially as the two sets of "savages" were not yet so closely intermingled as to be indistinguishable—at least in many parts of Fiji. It is unfortunate that the earlier European visitors to Fiji were not of the kind to observe and to leave proper records of their observations.

The earlier, Melanesian, occupants of Fiji had to some extent given way, but by no means readily and completely, to the Polynesian invaders. The former, not only in the mountain fastnesses difficult of access, but also in such of the islets as the local wind and weather conditions made difficult of access, retained their own distinct and simpler culture, their own thoughts, habits, and arts, long after the Polynesians had seized the more important places accessible to the sea, and had imposed much of their own more elaborate (but still "savage") culture on such of the Melanesian communities as they had there subjugated and absorbed.

The social organisation throughout Fiji remained communistic; but in the purely Melanesian communities the system was purely democratic (*i.e.*, without chiefs), while in the newer mixed Polynesian-Melanesian communities—as was natural when there had been intermingling of two unequally cultured races—there had been developed a sort of oligarchic system, in which the Melanesian commoners worked contentedly, or at least with characteristic resignation, for their new Polynesian chiefs.

Alike in all these communities custom enforced by club-law prevailed; but in the one case the administrative function rested with the community as a whole, while in the other it was usurped by the chiefs.

Though we are here to consider mainly the ideas, the mentality, of these people, it will be useful to say a few preliminary words as to their arts and crafts. The Melanesians during their long undisturbed occupation of the islands had undoubtedly made great progress, on lines peculiar to them, especially in boat

building, in which they excelled all other South Sea islanders, in the making of clubs and other weapons, and in otherwise using the timber, which grew more abundantly, and of better quality, in their islands than elsewhere. Meanwhile the Polynesians, in their earlier homes and long before they reached Fiji, had developed, in very high degree, corresponding but different and much more elaborate arts (and ideas) of their own. But, as we know from Captain Cook, the Polynesians, despite their own higher culture, from their Tongan homes, greatly admired and appreciated the special craftsmanship of the Fijians, and it was indeed this admiration which attracted the former from Tonga to Fiji; and when the Polynesians had gained footing in the Fijis they—quite in accordance with human nature—were inclined, for a time at least, to foster the foreign Fijian arts—if not Fijian ideas—rather than replace these by their own arts; and before the struggle, both physical and cultural, between the two sets of "savages" had gone far it was interrupted, and more or less definitely arrested, by the arrival and gradual settlement of the still more powerful, because civilised, white folk from the Western world.

In turning to the earlier (Melanesian) occupants of Fiji, and especially to the less advanced of these, to find the traces of which we are in search of the more primitive habit of thought, it must not be forgotten that even at the stage at which we begin to know about them they had made considerable advance, in their ideas as well as in their arts and crafts. They still used their most primitive form of club, but also made others of much more elaborated form; so, though the ideas which lay at the basis of their habit of thought were of very primitive kind, they had acquired others of more complex character.

Before going further may I say—and I sincerely hope that suggestion will not be misunderstood—that in the difficult task of forming a clear conception of the fundamental stock of thought which must have guided the conduct of the more primitive folk we must constantly bear in mind the parallelism (I do not mean necessary identity of origin) between the thoughts of the earliest human folk and the corresponding instincts (as these are called) noticeable in the case of some of the higher animals? I am particularly anxious not to be misunderstood; the suggestion is not that even the most primitive human folk were mentally merely on a par even with the higher animals, but that many, perhaps most, of the ways of thought that guided the primitive man in his bearing towards the world outside himself may be more easily understood if it is once realised, and afterwards remembered, that the two mental habits, however different in origin and in degree of development, were remarkably analogous in kind.

A similar analogy, in respect not of thoughts but of arts, may well illustrate this correspondence between the elementary ideas of men and animals. The higher apes occasionally arm themselves by tearing a young tree up by the roots and using the "club" thus provided as a weapon of offence and defence against their enemies. Some of the primitive South Sea islanders did—nay, do—exactly the same, or at any rate did so until very lately. The club—the so-called *malumu*—which the Fijian, then and up to the much later time when he ceased to use a club at all, greatly preferred to use for all serious fighting purposes was provided in exactly the same way, *i.e.*, by dragging a young tree from the ground, and smoothing off the more rugged roots to form what the American might call the business end of the club. But though the Fijian, throughout the period during which he retained his own ways, used and even preferred this earliest form of club, he meanwhile employed his leisure (which was abundant), his fancy, and his ingenuity, in ornamenting this weapon, and also in gradually adapting it to more and more special purposes, some of the later of which were not even warlike but were ceremonial purposes, until in course of time each isolated island or group of islands evolved clubs special to it in form, purpose, and ornament, and the very numerous and puzzlingly varied series of elaborate and beautiful clubs and club-shaped implements resulted. It seems to be in power of improvement and elaboration that lies the difference between men-folk and animal-folk.

Something similar may be assumed to have brought about the evolution of the ideas of these islanders. Starting with a stock of thoughts similar in kind to the instincts of the more advanced animals, the human-folk—by virtue of some mysterious potentiality—gradually adapted these to meet the special circumstances of their own surroundings, and in so doing ornamenting these primitive thoughts further in accordance with fancy.

In the Fiji islands this process of cultural development was probably slow during the long period while the Melanesians, with perhaps the occasional stimulus afforded by the drifting in of a little human flotsam and jetsam from other still more primitive folk, were in sole occupation; yet it must have been during this period and by these folk that the distinctly Fijian form of culture was evolved. But the process must have been greatly accelerated, and at the same time more or less changed in direction, by the incoming of the distinct and higher Polynesian culture, at a time certainly before, but perhaps not very long before, the encroachment of Europeans.

In order to realise as vividly as possible what were the earlier, most elementary, thoughts on which the whole detail of his subsequent "savage" mentality was gradually imposed, it is essential for the time being to discard practically all the ideas which, since the road to civilisation parted from that on which savagery was left to linger, have built up the mentality of civilised folk; it is essential to try to see as the most primitive Fijian saw and to conceive what these islanders thought as to themselves and as to the world in which they found themselves.

It seems safe to assume that the primitive man, absolutely self-centred, had hardly begun to puzzle out any explanation even of his own nature, still less of the real nature of all the other things of which he must have been vaguely conscious in the world outside himself. To put it bluntly, he took things very much as they came, and had scarcely begun to ask questions.

He was—he could not but be, as the lower animals are—in some vague way conscious of himself, and from that one entirely self-centred position he could not but perceive from time to time that other beings, more or less like himself, were about him, and came more or less in contact with him.

The place in which he was conscious of being appeared to him limitless. He did not realise that he could move about only in the islet which was his home, or perhaps even only in a part of a somewhat larger, but according to our ideas still small, island; if other islets were in sight from that on which he lived, these also would be part of his world, especially if—though such incidents must have been rare—he had crossed to, or been visited by strangers from, those islands—islands which lay between his own home and that which he spoke of as *wai-langi-lala* (water-sky-emptiness) and we speak of as the horizon. To him the world was not limited by any line, even the furthest which his sight disclosed to

him. Rarely, but still sometimes, strangers had come from beyond that line. Perhaps, too, he had some time heard that his ancestors had come from the somewhere which seemed beyond. Again, his ancestors of whom he had heard, and even some of the contemporaries whom he had seen, though no longer with him, except occasionally during his dreams, in bodily form, were somewhere, somewhere beyond that line of sight. Even he himself (in what were his dreams, as we say, but to him were part of his real life) habitually went beyond the line, and, so far as his experience had gone, returned each time to the island home.

Moreover, he did not doubt that this limitless region in which it vaguely seemed to him that he, and innumerable other beings, moved, extended not merely along what we speak of as the surface of the globe, but also, and equally, without any intervening obstacle, up into the infinite space above and beyond the sky. In short, to this primitive man the world, though the part of it to which he had access was so small, was limitless.

The thoughts of the dweller in this vague world, as to himself and as to the other beings of which from time to time he became conscious, must have been correspondingly indefinite.

He was, to a degree almost if not quite beyond our power of conception, a spiritualist rather than a materialist; and it is essential to get some idea of the extent and manner of his recognition of spiritual beings—and his corresponding non-recognition of things material.

In passing, I here disclaim, for myself at least, the use of the misleading word "belief" in speaking of the ideas of really primitive man—as, for instance, in the phrase the "belief in immortality." Possibly primitive men of somewhat more advanced thought, though not yet beyond the stage of "savagery," may have "believed" in spirits, in immortality, and so on; but it seems to me that at the earlier stage there can scarcely have been more than recognition (admittedly very strong recognition) of spiritual beings, and non-recognition of any beginning or ending of these spirits.

To return from this digression, Sir E. B. Tylor long since gave currency to the very useful word "animism," as meaning "the belief in spiritual beings," and this has been taken to mean that animism was the initial stage, or at any rate the earliest discoverable stage, of all religion. The primitive Fijian was certainly a thorough-going animist, if his extraordinarily strong but vague recognition of spiritual beings suffices to make him that; but I do not think that the ideas of that kind of the primitive "savage"—or, say, of the most primitive Fijian—before his ideas had been worked up into somewhat higher thought, during the long period while he was secluded in his remote islands, and before the advent of the Polynesians, had developed far enough to constitute anything which could be called "religion," though doubtless they were the sort of stuff which, had these folk been left to themselves, might, probably did, form the basis of the "religion" towards which they were tending.

Practically all human beings—savage and civilised alike—and, though in lower degree, even animal-folk, have in some degree recognised the existence of some sort of spiritual beings. The point, then, seems to be to discover what was the nature of the spiritual beings which the primitive Fijian recognised, but without understanding.

Anthropologists have recently defined, or at least described, several kinds of spiritual beings as recognised (even here I will not use the word "believed") by more or less primitive folk. There is, first, the soul, or the separable personality of the living man or other being; secondly, the ghost, or the same thing after death; thirdly, the spirit, which is said to be a soul-like being which has never been associated with a human or animal body; and, fourthly, there is, it appears, to be taken into consideration yet another kind of spiritual being (or something of that nature) which is the life of personality, not amounting to a separable or apparitional soul, which, it has been supposed, some primitive folk have attributed to what we call "inanimate things."

It seems, though I say this with all due deference, that this identification and naming of various kinds of spiritual beings, though it may hold good of animism at a higher stage, does not fit the case of the more primitive animist (say, that of the Melanesian in the very backward state in which, so far as we know, he first reached Fiji), for presumably he had not as yet recognised or differentiated between the various kinds just enumerated. He recognised something which may be called the "soul," which was the separable personality of the living man or other being. But he did not recognise—perhaps it would be better to say that he had not yet attained to recognition of—the ghost, or the same thing after death; for he had not even recognised any real break, involving change, at death. Nor, as I think, did he recognise a spirit, *i.e.* a soul-like being which had never been associated with a human or animal body; for he had no idea of any spiritual being which did not, or could not, on occasion associate itself with a human, animal, or other material body, nor seemingly had he reached the stage, labelled *animatism*, in which he would have attributed life and personality to things (which I take to mean things which are to us inanimate).

All that the most primitive man would recognise would be that he himself—the essential part of him—was a being (for convenience and for want of a better name it may be called "soul") temporarily separable at any time from the material body in which it happened to be, and untrammelled—except to some extent by the clog of the body—by any such conditions as time and space; he had found no reason to think that in these respects the many other beings of which from time to time he became aware (whether these were what we should class as men, other animals, or the things which we speak of as inanimate, such as stocks and stones, or bodiless natural phenomena, such as winds) differed from himself only in the comparatively unimportant matter of bodily form; moreover, it seemed to him that, as he himself could to some extent do all these, the other beings, and some perhaps even more easily, were able to pass from one body to another.

He felt that these "souls" were only temporarily and more or less loosely attached to the particular material forms in which they happened to manifest themselves at any moment, and that the material form in which the soul (and noticeably this held good even of his own soul) happened at any moment to be embodied was of little or no real importance to that soul, which could continue to exist just as well without as with that body.

Another point which it is important to note is the egoism of the savage man as distinguished from the altruism of the civilised man; for it was perhaps the beginning of the idea of altruism, of duty to one's neighbour, that gave the start to civilisation, and it was because the ancestors of the savage had never got hold of this fundamental principle altruism that they were left behind.

The uncivilised man, complete egoist as he was,

thought and acted only for his own personal interests. It is true that he was to a certain extent kind (as we might call it) to the people of his own small community, and possibly still more kind to such of the community as seemed to him more immediately of his own kindred. But this kindness was little more than instinctive—little more than a way of attracting further service. It is also true that on the occasions, which must have been very rare till a late period in the Melanesian occupation of Fiji, when strangers—*i.e.* persons of whom he had not even dreamed—came, so surprisingly, into his purview, he was sometimes civil or even hospitable to those strangers (it should not be forgotten that to him these were souls embodied by separable accident in material forms); but this would have been only on occasions on which he knew, or suspected, that these visitors were stronger than himself, and able to injure or benefit him.

Another point of great significance in the character of this primitive man was that he had no conception of ownership of property. To him all that we should class as goods and chattels, his land, or even his own body, was his only so long as he could retain it. He might if he could and would take any such property from another entirely without impropriety; nor would he resist, or even wish to resist, the taking from himself of any such property by any one who could and would take it.

Again, the primitive man must have been far less sensitive to pain, and far less subject to fear, than the normal civilised man. I do not mean that the primitive Fijian was without the ordinary animal shrinking from physical pain, but that he cannot have been nearly as sensitive even to physical pain as is the more sophisticated man; nor had he the same mental pain, the same anticipation and fear of pain, that the civilised man has.

Having thus dealt with some of the more important points in the character of the primitive Fijian, I propose next to consider how far these suffice to account for some of the more "savage" conditions under which these islanders when first seen were living.

Cannibalism claims the first mention, in that, though the practice has been recorded from many other parts of the world, it is commonly supposed to have been carried further in Fiji than elsewhere.

Here, however, it is at once necessary to point out that the outbreak of cannibalism in Fiji in the first half of the last century was not due to any innate and depraved taste on the part of the Fijians, and that the practice to the degree and after the fashion of which the story-books tell was not natural to the Fijian, whether of Melanesian or Polynesian stock.

It is probable, even perhaps certain, that all the Fiji islanders occasionally ate human flesh before the coming of white men to the islands; but it was only after the arrival of the newcomers that this practice, formerly only occasional and hardly more than ceremonial, developed into the abominable orgies of the first half of the last century. The first Europeans to set foot—about 1800—and to remain in the islands for any time were the so-called "beachcombers." At first, at least, these renegades from civilisation, to secure their own precarious position and safety, contrived to put themselves under the patronage of some one or other of the great native chiefs, who would be Polynesians, and assisted and egged on these chiefs in their then main occupation of fighting other great rival chiefs, also Polynesians, and raiding the less advanced Melanesians of the surrounding districts. The guns and ammunition which the beachcombers, in some cases at least, brought with them or managed to procure, and the superior craft which they had imbibed from civilisation, greatly assisted them in this immoral purpose. Consequently a habit of cruelty, new to the Fijian, was implanted and developed, especially in the Polynesian chiefs. It became more and more a fashion for the greatest native warriors, thus egged on, to vie with each other in the number of their victims and in the reckless cruelty with which these were killed. Doubtless at first the victims were opponents killed in fight, sometimes great rival chiefs and sometimes mere *hoi polloi* who had been led out to fight, probably not very reluctantly, for their chiefs. Incidentally more and more people were killed; and the bodies of the slain were conveniently disposed of in the ovens. A taste for this food was thus developed in the chiefs—though this seems, for a time at least, to have been confined to the great chiefs, most of those of lower status, and all women, refusing to partake, at any rate until a later period. Before long, when the number of the killed ran short, the deficiency was made up by clubbing more and more even of their own people, until eventually the great native warrior took pride in the mere number of those he had killed and eaten.

It seems probable that even the coming of the missionaries, who first reached Fiji thirty or forty years after the earliest beachcombers, and at once began almost heroic efforts to stop cannibalism, thereby to some extent temporarily even aggravated the evil. For the chiefs, in their characteristic temper of gasconade, killed and ate more and more unrestrainedly, in mockery of the missionaries and to show what fine fellows they thought themselves to be.

To return from this digression into a somewhat distasteful subject, cannibalism as practised by the Fijians before the coming of white man was very different, and, from the Fijian point of view—if I may say so without fear of being misunderstood—not altogether indefensible. It must be remembered that there was, as it were, no killing in our sense of the word involved, merely a setting free from the non-essential body of the essential soul, which soul survived just as well without the body as with it.

Note that the soul must have been considered as in some way and for a time still associated with its late body if, as is commonly and perhaps rightly held, the slayer sometimes ate some part of the body of the slain in order to acquire some of the qualities of the slain.

Again, there can be little doubt that men were sometimes killed for sacrificial purposes, the material bodies of the victims being placed at some spot (perhaps the tomb) considered to be frequented by the disembodied spirit of some ancestor for whom it was desired to provide a spirit attendant. It may be noted that this sacrificial use of the body might be combined with an eating of the same body when once it had served its first purpose of attributing the spirit which had been in it to the service of the honoured ancestor.

It has been laid to the charge of the Fijians (as to that of many other folk of savage and even of civilised culture) that they habitually killed strangers, especially such as had been washed or drifted to the islands by the sea—who, in early times at least, must have been almost the only strangers to arrive. The charge, like that of cannibalism, has been exaggerated, and the facts—as far as there were any—on which this charge was founded have been misunderstood.

Here, again, the attitude of the Fijian in this respect was scarcely different from that of the lower animals in similar circumstances. The Fijian knew of no reason to be glad of the arrival of strangers, unless these could, in one way or another, be useful to him; and, as has already been explained,

he knew of no reason why he should not make the best use possible of the stranger, of his body or his spirit, separately or together.

While, as must have been the case in earlier times, the newcomers were dark-skinned men like himself, the Fijian might without the slightest prick of conscience separate their bodies from their spirits, and dispose of the body or the spirit separately; or without effecting this separation, he might simply enslave the newcomers; or, again, if he suspected that the newcomers were too strong for him, he might yield himself to them as a slave.

And later, when Europeans began to arrive, sometimes as refugees from passing ships and sometimes as survivors from ships wrecked on the surrounding reefs, the bearing of the Fijian towards this new kind of stranger would have been on the same principles, only that in this case the newcomers, being of far less readily understood kind, would be regarded with more suspicion and also more respect. I believe that very seldom, if ever, was an inoffensive white man, wrecked sailor or other, killed, or treated with anything but kindliness and courtesy, even though the wrecked man's property might naturally be appropriated by the natives. It was only when white-skinned strangers became commoner, and frequently more offensive, and when familiarity had bred contempt, that they were killed, as nuisances, and, especially during the great outbreak of cannibalism, were eaten.

This point in the bearing of the islanders to white men might be further illustrated by a circumstance which, to my surprise, I have never found mentioned, *i.e.*, that during the whole period while the missionaries were, with a rashness only justified by the circumstances, testifying against the natives in Fiji not one of these was killed, until at a much later period, when European influence was all but predominant in Fiji, Baker was killed and eaten in very special circumstances.

If it were possible to ascertain in each case the facts as to the reception by "savages" of the first white men they saw, it would almost certainly be found that the reception was apparently kindly, though this kindness may really have been due to fear and not to charity. It was, however, quite probable that at any moment the savage might find that his dread of the white man was unfounded, and in that case he might kill him (*i.e.*, separate his soul from his body) without hesitation, and after doing this his fear—he probably never had any affection for him—of the disembodied spirit of the white man might be as great, or even greater, than before.

Incidentally it may here be noted, as a further curious point, that a Fijian who thus quite remorselessly set free the soul of a stranger from its body would probably not often and not for long in his dreams be revisited by his victim, if a native; and perhaps not even if the victim were a white man, unless very remarkable. In other words, the victim survives only just so long as he is remembered. Captain Cook, we know, survived for very long, perhaps does so still; few, if any, of such beachcombers as were later killed in Fiji survived for any length of time; and the innumerable natives who were drifted or washed to one or other of the islands must for the most part have passed from memory soon after they were killed.

It has been suggested that the killing of strangers may have been for the purpose of preventing the introduction of disease; and it is certain that, perhaps even before the coming of white men, the islanders recognised that the advent of strangers was curiously often and most disastrously followed by the introduction of new diseases, either real diseases or at least some queer, unexplained influence which has so often made life not worth living for savages where white strangers have been.

The Fijians were scarcely more notorious for cannibalism than for theft—and almost as undeservedly. There is scarcely an account of the visit of a European ship in early times to any of the islands which does not mention that the islanders who came aboard took whatever they fancied, either quite openly, or, if furtively, then without evincing anything like shame when discovered. This habit, which the explorers naturally called theft, was but the manifestation of a South Sea custom, due to the entire absence of any idea of personal property, which in Fiji is called keri-keri. To keri-keri was to take whatever you wanted and could take without the previous holder of the property preventing you. In old days no Fijian doubted his own absolute right to keri-keri, nor did he feel the very slightest shame in thus (as we should say) "depriving another of his property," or "stealing"; and even to this day the Fijian, provided that he is not really Europeanised, will keri-keri without shame. In short, the idea of ownership and individual property never occurred to the natural Fijian. He took what he wanted, and was strong enough to take. But, on the other hand, he yielded up, practically without reluctance, whatever another stronger or cleverer than himself wanted and was able to take from him.

Of the many other charges of "savagery" made against Fijians, I can, in the time at my disposal, deal with but one more, that as to their strange and gruesome habit of celebrating great occasions by killing their own folk. When a Fijian chief died, as we should say, or, as it seemed to the surviving natives, when his soul left the body which it had for a time used, his widows, and other of his kindred and dependants, unwilling to be left behind, were strangled, often, indeed, helped to strangle themselves, that their bodies might be put into the graves, while their souls went gladly with that of the chief whom they had been accustomed to follow.

Again, when a chief built a house, some of his dependants, whom the great man told off for the purpose, willingly stepped down into the holes which had been dug for the house-posts, and remained there while the earth was filled in on them, and continued thereafter as permanent supporters of the house.

Again, there is a tradition, which at least was not incredible to the natives, that a great chief one day went a-fishing, and caught many fish. Two brothers of humbler rank who happened to have come down to the same waterside, also to fish, were less successful. The chief, in a characteristic freak of generosity, presented his best fish to the elder of the two brothers, who, strictly according to Fijian custom, accepted the gift, but felt bound to make an immediate return, but he had nothing to give. Thereupon the younger brother, at his own suggestion, was clubbed by the elder, and his body presented to the chief in token that his soul would thereafter serve that chief.

It is even said that when yams and other vegetables were brought in as food for the chiefs by the dependants who had grown them for that purpose, the food-bearers, if there was a scarcity of fish or other suitable accompaniment for the vegetable diet, were themselves clubbed and their bodies eaten. This particular atrocity probably happened only after the habit of cannibalism had, as already explained, been unnaturally intensified. But the story is noteworthy in that the food-bearers are not represented as in any

way dreading or shirking the use to which their bodies were put.

In all these and similar cases it is to be noted that the victims (as we are naturally inclined to call them) were more or less indifferent, if, indeed, they were not eagerly consenting parties, to the use (cruel as it seems to us) made of their material bodies. Thus the widows were eager to be strangled, and often even helped to do the deed, in order that they—all that was essential of them, *i.e.* their souls—should rejoin the deceased. Similarly those others who were killed on the occasion of the funeral were quite willing to give their bodies, which seemed of comparatively little importance, as "grass" to be added to the cut fern and other soft material on which the body of the deceased chief was couched in the grave; and quite willingly the men told off for that purpose stepped down into the holes in which the house-posts were grounded, that they, or rather their bodies, might thereafter hold up the house, while their souls enjoyed life much as before but without the encumbrance of the body. Others, again, contentedly grew *taro* for the chiefs to eat, and carried it in when ripe, thinking it of little importance that their mere bodies might be eaten with the *taro*.

In conclusion, having endeavoured to realise for myself, and to show you a glimpse of the enormous, scarcely conceivable difference in habit of thought, and consequently in character, which separates the savage from the civilised man, I will offer a suggestion which seems to me possibly the most important outcome of my personal experience, now closed, as an anthropological administrator in tropical places where Eastern and Western folk have met, and where the inevitable clash between the two has occurred.

In such places and circumstances the result has too often been that sooner or later the weaker folk—those whose ancestors have been age-long "savages"—have died out in the presence of those whose ancestors long ago turned from "savagery" to civilisation. This dying out of the weaker folk has happened even when the stronger people have done their best to avoid this extirpation.

The real ultimate cause of "the decrease of natives" when in contact with civilised folk lies, perhaps, in the difference in hereditary mentality—in the incapacity of the "savage" to take on civilisation quickly enough. However sedulously the missionary, the Government official, and others who take a real interest in so doing, may teach civilised precepts to the essential savage, the subject of this sedulous case—however advanced a savage culture he may have attained—will, at least for many generations, remain a savage, *i.e.* for just so long as he is under influence of the civilised teacher he may act on the utterly strange precepts taught him, but away from that influence he will act on his own hereditary instincts.

The manner in which the native dies out—even when well looked after—varies. He may be killed out by some disease, perhaps trifling, but new to him, with which he does not know how to cope, and with which—if he can avoid so doing—he simply will not cope in the ways which the civilised man would teach him; or he may be killed out by the well-meant but injudicious enforcement on him of some system of unaccustomed labour; or, again, he may die out because deprived of his former occupations (*e.g.* fighting and the gathering of just so much food as sufficed for him) and thus restricted to a merely vegetative existence; or in many other more or less similar forms his extermination may come about.

But all such effective causes are reducible to one, which is that he is not allowed to act on his own hereditary instincts, that he cannot at all times have, and often would not use, judicious and disinterested guidance from civilised folk, and that consequently he, the "savage," cannot and too often does not care to keep alive when in the presence of civilised folk.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY PROF. BENJAMIN MOORE, M.A., D.Sc., F.R.S., PRESIDENT OF THE SECTION.

The Value of Research in the Development of National Health.

THE history of medical science presents to the curious student a remarkable development commencing in the latter half of the nineteenth century, and one worthy of special study, both on account of the light that it sheds on the present position and the illumination it affords for future progress.

If any text-book of medicine or treatise on any branch of medical science written before 1850 be taken up at random, its pages will reveal that it differs but little from one written a full century earlier. If such a volume be compared with one written thirty-five years later, it will be found that the whole outlook and aspect of medicine have changed within a generation.

Erroneous introspective dreams as to the nature of diseases, as "idiopathic" as the many strange maladies which their authors are so fond of describing have been replaced by fast-proven facts, and medicine has passed from an occult craft into an exact science based upon experimental inquiry and logical deduction from observation.

What caused this rapid spring of growth, after the long latent period of centuries, and are we now reaching the end of the new era in medicine, or do fresh discoveries still await the patient experimentalist with a trained imagination who knows both how to dream and how to test his dreams?

It is but a crude comparison that represents the earlier age as one of empiricism and imagination, and the later period as one of induction and experiment. Empiricism has always been of high value in science, it will ever remain so, and some of the richest discoveries in science have arisen empirically.

Imagination also is as essential to the highest scientific work to-day as it was a century ago, and throughout all time the work of the genius is characterised in all spheres of human endeavour by the breadth and flight of the imagination which it shows. The great man of science, whether he be a mathematician, a physicist, a chemist, or a physiologist, requires imagination to pierce forward into the unknown, just as truly as does the great poet or artist. Also, the inspired work of poet or painter must be concordant with a system of facts or conventions, and not outrage certain canons of his art, as certainly as the true and lasting work of the man of science must accurately accord with natural laws.

The man of science is as little able to prove the fundamental truth or existence of the groundwork upon which modern physical, chemical, and physiological theories are built, as the artist is to prove the ethics, or perfect truth, or perfect beauty, of those conventions upon which poetry, painting, or that great group of studies termed the "humanities" find their basis. But the artist or philosopher knows that, using these conventions as the best at present discovered, he can produce works of which the beauty and consistency appeal to all educated human minds capable of appreciation. Similarly, the conventions of natural science, properly understood, appeal to the

imagination of the man of science, call forth new ideas to his mind, and suggest fresh experiments to test those ideas; or, a chance empirical observation of an experimental nature, which without theory and scientific imagination would remain isolated and sterile, placed in relationship to the rest of the scheme of science, awakens thought, and may lead to a fresh departure and a long train of important discoveries.

It was this correlation of the imagination with experimentation and the tracing out of relationship from point to point so as to develop the evolution of phenomena that characterised the science of medicine when new-born about seventy years ago, and differentiated it from the older nosological medicine in which imagination and experimentation, while both existing, seemed to possess independent existences and pay little regard the one to the other.

It seems well-nigh forgotten nowadays by the majority of people that science and religion originally began together from a common thirst for knowledge, and usually in the same type of mind endowed with a divine curiosity to know more of the origin and nature of things.

Every great religion worthy of the name contains some account of the natural history and creation of the world, in addition to its metaphysical aspects, and reflects the degree of knowledge of natural science possessed by the nation in which it arose at the time of its birth.

The fundamental error throughout the ages of human conceptions both in science and religion was that of a non-progressive world to which a stereotyped religion, or science, could be adapted for all time. Perfection was imaged where perfection, we are now happy to realise, was impossible, and, believing in this imaginary perfection and that all things new deviating from it were damnable, men were prepared to burn one another at the stake rather than allow error to creep into the world in either science or religion. Thus there have been martyrs for the scientific conscience just as for religious belief, and at this distance in time we can perhaps better understand both inquisitor and martyr and realise that both were fighting for great ideals.

Evolution has taught us that as knowledge broadens we must be prepared to have wider vision and abandon old theories and beliefs in the new-born light that makes the world better to-day than it was yesterday, and that also will show things up to our mental vision more clearly to-morrow than they stand out to-day. To the members of any great craft, or profession, or religious order, this scientific outlook which accepts as fundamental a progressive world, and insists that its votaries should adapt their lives to such a doctrine, is peculiarly difficult of assimilation. Routine fixes all men, and so when any new discovery appears to demand change from that order to which the mind has become accustomed, it is immediately looked upon with suspicion, and there being little plasticity of mind remaining, it is rejected as heretical or revolutionary after but scant critical examination. The cry of the craft in danger has been used efficaciously on many occasions since the days of the Ephesian silversmiths, nor is such a cry at once to be set down to pure selfishness. A craft is often worth preserving long after the forces which have called it into being have commenced to slumber, and conservatism of this type is at times an important factor in social progress. However, there are certain limits which must not be surpassed, room must be made by adaptation for the new knowledge, or it will establish a craft of its own iconoclastic to much worth preserving in the older system.

It is important to insist upon these limitations, because a too reactionary spirit abroad in medicine between 1860 and 1880 prevented the world from benefiting from those remarkable discoveries by Pasteur and their proposed applications by Lister, which laid the foundations of modern medicine and modern surgery. These pioneers of the new age in medical science had to wage for many years a stern and bitter fight against the strong forces of ignorance and prejudice. But for this illogical resistance by men who would not even test the new discoveries, and instead spent their time in sneering at the new geniuses who had leadership to give the world, France and Germany would have been saved many thousands of brave lives in the great war of 1870–71. Even thereafter, the slow struggle continued of the few who knew against the many who refused to be taught, and a perusal of any orthodox text-book of medicine published between 1875–80—that is, more than a decade after Pasteur's great discovery—will show that the etiology of scarcely a single infectious disease had become known, and that medical science was, for example, as ignorant of the nature of tuberculosis as we are to-day of the nature of carcinoma. Take, as an example, the following quotation from a well-known text-book of the theory and practice of medicine published in 1876: "It is now, however, generally admitted that tubercle is no mere deposit, but, on the contrary, a living growth as much as sarcoma and carcinoma are living growths." The tubercles were the only initial lesion observed, the infecting organism was entirely unknown, and the pathologists of this comparatively recent date argued at length as to whether tubercles were to be classed as "adenomata" or were something *sui generis*.

There is a gleam of sunlight for the future in this retrospect at the ignorance of the past, for, if men were as ignorant regarding tuberculosis thirty-eight years ago as to-day they are about cancer, then it may be argued that a generation hence as much may be known about cancer as is known now about tuberculosis.

It is particularly important at the present moment, when so much interest is being taken in national health, to point out the urgent necessity of allowing as little lagging behind as possible to ensue between the making of discoveries and the practical application of the results by organised national effort for the well-being of the whole community.

It must sadly be admitted that it is craftsmanship in imaginary danger fighting hard for the old methods unchanged which were in vogue fifty years ago that stands most prominently in the way of advance. As great a harvest as that which followed the application of the principle of antisepsis in surgery awaits the application of the self-same principle in national sanitation to-day, but the very profession which ought to be urging forward the new era apparently stands in dread of it, and seems to prefer to reap its harvest from disease rather than to seize the noble heritage won for it by the research of pioneers and so stand forth to the world as the ministry of health. Fortunately it cannot be, the bourne has been passed, and there is no going backward. The advances that have already been made have awakened statesmen and people alike to the needs of the situation, and all have resolved to be disease-ridden no longer. The laws of health must be made known to the people at large, and schemes laid before them for a national organisation for the elimination of disease. Disease is no longer an affair of the medical profession, it is a national concern of vital importance. The problem is not a class question, all humanity stands face to face with it now in the light of modern research as it never has faced it before. It has been realised that disease never can be conquered by private bargains for fees

between individual patient and individual doctor. Research into diseases of unknown causation cannot be subsidised upon such individualistic lines, and in the case of diseases of known etiology and modes of propagation, the passage of disease from individual to individual cannot be controlled by such private methods as that of the afflicted individual subsidising the doctor for his own protection. Cost what it may, a healthy environment must be produced for the whole mass of the population, and the laws of physiology and hygiene must be taught not only to medical students, but to every child in every school in the country. People cannot live healthy lives in ignorance of the fundamental laws of health merely by paying casual visits to physicians, and no one class in the community can be healthy until all classes are healthy.

The problem of national health is one of peculiar interest to physiologists, and to the exponents of those experimental branches of medical science which have sprung from the loins of physiology, for it was with them that the new science of medicine of the last fifty years arose, and they ought to be the leaders of the world in this most important of all mundane problems.

It is well worth while to consider our opportunities and responsibilities and raise the question whether our present system and organisation are the most suitable for attaining one of the most sublime ambitions that ever appealed to any profession. By definition, our science studies the laws of health and the functions of the healthy body, therefore it is ours to lead in the quest for health. Is this object best achieved if we confine ourselves to research in our laboratories, and to the teaching of the principles of physiology to medical students, while we leave the community as a whole uninstructed as to the objects of our research and its value to every man, and trust the medical students whom we turn out to communicate, or not communicate as they choose, the results of their training and our research to the world at large?

There is little question that much of the ignorance abroad in the world, and much of the fatuous opposition to our experimental work and research, arise from this aloofness of ours. Here also lies the cause of much of the latent period in the application of acquired knowledge to great sociological problems, and the presence of untold sickness and death which could be easily prevented if only a scientific system of dealing with disease could be evolved.

The position occupied by men of science in medicine at the present day is largely that of schoolmasters to a medical guild, and even at that, one constructed upon lines which have grown antiquated by the progress of medical science. It ought now to become the function of the man of science to re-model the whole system so as to fight disease at its source. The whole situation at the moment calls out for such a movement. On the one hand, there exists a widespread interest on the part of an awakened community in health questions, evidenced by recent legislation dealing with the health of school children, with the health of the worker, with the sanitary condition of workshops, with the questions of maternity and infant mortality, and with the communication of infectious diseases. On the other, there is chaos in the medical organisation to meet all these new demands, and the ample means recently placed at the command of the nation and of municipal authorities are being largely wasted by overlapping and misdirection for lack of skilled leadership. Surely it is a time when those who have laid the scientific foundations for the new advances should take counsel together, assume some generalship, and show how the combat is to be waged, not as a guerilla warfare, but as an organised and coordinated campaign.

There are two essentials in the inception of this organised campaign against disease on a scientific basis. The first is to demonstrate clearly to the public mind that modern scientific medicine arose from the experimental or research method, that it was only when experimental observation of the laws of health and disease, in animals and man, commenced on an organised and broadcast basis that medicine and surgery leaped forward and the remarkable achievements of the past fifty years began. Also that it is only by the organisation and endowment of medical research that future discovery and advancement are possible. The second essential is to convince the public that a national system must be evolved placing medical science and medical practice in coordination, so that the discoveries of science may be adequately applied in an organised scheme for the prevention and treatment of disease. The method in which discoveries have been made in the past suggests an amplification and organisation along similar lines for the future, and the banishment of many diseases by public health work in the past suggests that it is more efficiently organised and widespread public health work in the future, extended from the physical environment to the infecting individual, that will be most fruitful in banishing other diseases.

If it be queried by anyone here, what has physiology to do with disease, it may be replied that the question comes at least fifty years too late. The methods evolved first by physiologists in experimentation upon animals have become the methods of all the exact sciences in medicine. Bacteriology is the physiology of the bacterium, and the study of protozoan diseases the physiology of certain groups of protozoa. Organotherapy had its origin in physiology, and many of its most brilliant discoveries were made by physiologists, and all by men of science who used physiological methods. Serum therapy, experimental pharmacology, and the great problems of immunity all arose from the labours of men with expert training in physiology who branched out into practical applications achieved by the extension of the experimental, or research, method. The modern methods of medical diagnosis and the brilliant technique of contemporary surgery, what has opened the door to these but the experimental method? From the days of the first successful abdominal operation to the present day, research in laboratory or in the operating theatre has pioneered the way, and the sooner this simple truth is known to all men the better for medical science. Every time any surgeon first tries a new operation there is in it an element of experiment and research of which the ethical limits are well known and definable, and any person who logically thinks the matter out must see that it is the research method which has placed the science and art of surgery where it stands to-day. Exactly the same thesis holds for medicine. How could any physician predict for the first time, before he had tried it experimentally on animal or man, the action of any new drug, the effect of any variation in dosage, the result of any dietary, of the employment of any course of physical or chemical treatment, or of anything in the whole of his armamentarium? Yet the public are rarely told any of these wholesale truths, but are rather left to speculate that each medical and surgical fact sprang forth as a kind of revelation in the inner consciousness of some past genius in medicine or surgery, who, in some occult way, knew of his own certain foreknowledge what would be the definite effect of some remedy or course of treatment before he tried it for the first time on a patient, or perhaps had the ethical conscience and genuine humanity to test it

on a lower animal before he administered it to man.

It may, in short, be taken as an axiom of medical science that everything of value in medicine and surgery has arisen from the applications of experimental research. Nor can future advance be made by any other method than the research method. It is true that accident may teach occasionally, as it did, for example, in the dreadful burns unwittingly inflicted on themselves and patients by the early experimenters in X-ray therapy and diagnosis. But accident is only the most blundering type of experimentation, and results obtained by its chance agency do not really invalidate the universal law that man only learns by experience, or, in other words, by research. Research is, after all, only the acquisition of fresh experience by the trained expert, usually led on to his experiment by inductance from other known facts.

It has been said above that all that is valuable in medical science has been acquired by research; the converse may now be pointed out, that much that was valueless, dangerous, and even disgusting in medicine in earlier days was incorporated into the medical lore of the time, and often remained there for generations, stealing lives by thousands, because physicians had not yet adopted the research method, and so based their practice upon ignorant and unfounded convention. It is noticeable in literature that up to somewhere in the beginning of the nineteenth century physicians and surgeons were often as a class looked upon by scholars and educated people with a certain amount of contempt. There were notable and fine exceptions in all ages, but, taken as a whole, the profession of medicine was not held in that high esteem and admiration that it is amongst all classes to-day. Take, for example, Burns's picture of Dr. Hornbrook, or Sterne's account of Dr. Slop in "Tristram Shandy," and similar examples in plenty are to be found in the Continental literature. The reason for the change is to be found in the comparative growth of medical science as a result of the research method. The physicians of those days were very often ignorant quacks employing the most disgusting and dangerous remedies, or methods of treatment, based upon no experimental knowledge and handed down in false tradition from ignorant master to ignorant and often almost illiterate apprentice. It is only necessary to peruse the volumes written on *materia medica* of this period to shudder at the nature of the remedies apparently in common use; the details are unfit for modern publication.

Even in the first half of the nineteenth century patients were extensively bled almost to exhaustion in a vast variety of diseases in which we now know with certainty that life would be endangered by such treatment and chance of recovery diminished. Thus, in a text-book published in 1844 by the professor of medicine in the most famous university in medicine of our country, and a physician in ordinary to her Majesty Queen Victoria, it is said that in the treatment of pneumonia "the utmost confidence may be placed in general blood-letting, which should always be large, and must almost always be repeated sometimes four or six times, or even oftener. Blistering and purging, under the same cautions as in the bronchitis, are to be employed; and two other remedies have been much recommended—opium, especially combined with calomel, and the solution of tartar emetic." It seems scarcely credible to us nowadays that about this same period a low diet, blood-letting, emetics, and purgatives were employed as a treatment in phthisis; yet such is the case. It is in keeping with the above, and in strange contrast to modern treatment, to find it recommended that if the patient cannot winter abroad he is ordered "strict confinement within doors in an artificial climate, as near as possible to 60° Fahr., during at least six months of the year in Britain." From the text-books of medicine of this period, only seventy years back, instances of wrongful and even dangerous treatment in most of the important diseases might be produced. There is no basis of accurate scientific knowledge of physiology, biochemistry, or bacteriology underlying the visionary notions about disease. The real causes of the diseases being obscure, they are commonly set down to so-called diatheses or habits such as the "hæmorrhagic diathesis" or the "scrophulous habit." Also, the action of infective organisms and the intimate relationships in regard to infection of members of the same family being unknown or forgotten, such "habits" are erroneously set down as hereditary. When there is no other channel of escape, the word "idiopathic" is coined to cover the ignorance of the learned.

If now we pass onwards about thirty years in time, halving the distance between the above period and our own time, and consult an important text-book of medicine published in 1876 by a fellow of the Royal College of Physicians, a physician and lecturer at a famous London medical school, and a lecturer on pathology and physiology, we find that the progress attained by research in physiology and physiological chemistry, and a growing belief in the possibility of infection in many diseases by the micro-organisms, now demonstrated so clearly in certain cases by Pasteur and his followers, have commenced to do their beneficent work in medical practice. The heroic bleedings and leechings and the scarcely less violent druggings with strong drugs have disappeared. The patient is less harassed by his doctor, who is more content to assist the natural processes of recuperation as his knowledge of applied physiology and hygiene teach him, rather than to thwart them and to lessen resistance as his predecessor often did a generation ago, when he knew no physiology and less hygiene. Still, the comparison between the text-book of even forty years ago and one of the present day shows a wonderful advance, all flowing from the use of the research method in the intervening years, both in knowledge of the origins and in the treatments of the diseases.

Time and space forbid going into details, but the whole of serum-, vaccine-, and organo-therapy were unknown, with the single exception of vaccination for variola. Enteric fever has been separated from typhus, but its etiology is still obscure, and, to a large extent as a consequence, the mortality from it is 15 to 16 per cent., or quadruple present-day figures, and it is one of the commonest of diseases. The cause of diphtheria is unknown, although it is now recognised as a "contagious" disease, and as yet research in bacteriology has supplied no cure for it. The unity of the various forms of tuberculosis is unsuspected, the infecting organism is unknown, and, as a result, it is not even recognised as an infectious disease, and heredity figures most strongly in a dubious etiology, leading up to a vacillating treatment. Pneumonia is not recognised as due to a micro-organism, and is described as one of the "idiopathic" diseases. The cause of syphilis, and its relationship to *tabes dorsalis*, and general paralysis are unknown, and generally it may be said that the causes of disease are either entirely unknown or erroneously given in at least three-quarters of the very incomplete list of diseases that are classified and described.

This, after all the centuries, was the doleful position of medical science in the year 1876, when suddenly light began to shine upon it, brought not by the agency of any member of the medical profession, but by a physiological chemist, and he was led to his great discovery, not in an attempt to solve some problem of practical medicine, but by scientific observations devoted to an apparently purely philosophical critical research into the supposed origin of life in a particular way.

It was the experimental or research method in biochemistry supported by physiological experiments on animals which, in the hands of Louis Pasteur, laid the foundations of true knowledge, and transformed medicine from what has been described above into the glorious, living, evolving science that we possess to-day.

The men who fought side by side with Pasteur in his famous struggle against orthodoxy in medicine as represented by the leading physicians and surgeons of the period between 1860 and 1880 were mainly chemists, biologists, and physiologists, such as Claude Bernard, Paul Bert, J. B. Dumas, Biot, Belard, and Sainte-Claire Deville, in his own country, and Tyndall and Huxley in ours. A few physicians and surgeons of scientific training in France and England recognised the importance of his discoveries, such as Alphonse Guérin, Villemin, and Vulpian, in his own country, while Lister in ours was already at work, had experimented widely and wrote his memorable letter of congratulation to Pasteur in 1874, informing him of the work he had been doing in introducing antiseptic surgery in England during the preceding nine years. Against this intrepid little band of experimental men of science were massed all the batteries of orthodox medical nescience served by the distinguished physicians and surgeons of the time; but truth is mighty and must prevail. Davaine applying Pasteur's principles in a medical direction had found out the bacterial origin of anthrax, and although he was violently attacked by oratorical arguments in opposition to experimental proofs, and accused, as many physiologists are to-day, of having "destroyed very many animals and saved very few human beings," his facts held fast, and combined with the later experiments of Koch and of Pasteur, not merely established the etiology of anthrax as we know it to-day, but gave a support and forward growth to that new-born babe, bacteriology, which without such animal experiments could never have grown into the beneficent giant that it is to-day in all its glorious strength for the weal of humanity.

Pasteur himself meanwhile was hard at work in the small ill-equipped laboratory of physiological chemistry of the Ecole Normale at Paris, from which the fame of his discoveries began rapidly to spread and shed a new light forth on the medical world. Pasteur at this stage had already largely rehabilitated the national prosperity of his own country by his successful researches on silk-worm disease and on fermentation maladies and the diseases of wines. All this effect upon national industries, it is to be noted, followed on from an inquiry of apparently no practical importance on spontaneous generation. He now turned his genius towards disease, there also utilising the same discovery arising from a research that contained at first sight no possible applications to disease, and the remainder of his life was devoted to the extension of these studies. The subsequent history of this discovery is the science of bacteriology with all its ramifications and manifold applications in industry, in agriculture, in medicine, and in public health, investigated by the experimental method by thousands of willing workers all over the civilised world. Who but the ignorant Philistine, who knows not what he prates about, can deny the profound influence of animal experimentation, and the philosophic application of the principle of research upon the history of the world?

Let us now, from the vantage-point of the present, look back at the past and glean from the study of the manner in which this science took origin some knowledge to guide us, first, as to how research may be fostered and encouraged in the future, and, secondly, as to how the results of research may be applied for social advantage.

The first and perhaps the finest thought of all is that research must be pursued with the highest ideals of the imaginative mind apart from all desired applications or all wished-for material advantages. If we might personify nature, it would seem that she does not love that researcher who only seeks her cupboard, and never shows her finest treasures to him. She must be loved for her own beauty and not for her fortune, or she will ne'er be wooed and won. Not even the altruistic appeal of love for suffering mankind would seem to reach her ears; she seems to say: "Love me, be intimate with me, search me out in my secret ways, and in addition to the rapture that will fill your soul at some new beauty of mine that you have discovered and known first of all men, all these other material things will be added, and then I may take compassion on your purblind brothers and allow you to show them these secret charms of mine also, so that their eyes may perchance grow strong, and they, too, led hither by you, may worship at the shrine of my matchless beauty." By all the master discoveries in all the paths of science, nature is ever teaching us this great doctrine to which we have closed our ears so long. She tells us the creation of the world is not finished, the creation of the world is going on, and I am calling upon you to take a part in this creation. Never mind that you cannot see the whole, love that you see, work at it, and be thankful that I have given you a part to play with so much pleasure in it, and so doing you will rise to the highest ideal.

This is religion with thirst for knowledge as its central spring; does it differ much from those aspirations which have made men of all nations worship throughout all the ages? Anthropology teaches us that the religious system of a race of men gives a key to their advancement in civilisation. If this be so, growth in natural knowledge must elevate our highest conceptions, furnish purer ideals, and give us more of that real religion that is to be found running so strongly in the minds of great individuals, such as Isaac Newton, Michael Faraday, Louis Pasteur, Auguste Comte. A great man may be strongly opposed to the orthodox creeds of his day, he may even sneer at them, he may be burnt at the stake by their votaries, and yet be a man of strong religious feelings and emotions which have furnished the unseen motive power, perhaps unsuspected even by himself, that leads to a whole life of scientific heroism and enthusiasm.

The practical lesson for us to learn from all this is that we must consider research as sacred and leave it untrammelled by fetters of utilitarianism. The researcher in functional biology, for example, must be left free to pursue investigations as inspiration leads him on any living structure from a unicellular plant to a man, and must not be expected to devise a cure for tuberculosis or cancer. In his research he must think of something higher even than saving life or promoting health, or he is likely to prove a failure at the lower level also.

As an example of the wrong attitude of mind towards science, there may be taken the point of view of those utilitarians who complain of the amount of time and discussion at present being given to

the problem of the origin of life. These wiseacres with limitations to their brains say "that is an insoluble problem, we shall never get to the bottom of it, let us simply assume, since it is here, that life did originate somehow, and, taking this as an axiom, proceed to some practical experimental problem; the origination of life does not lend itself to experimental inquiry."

Now it is, strange to say, just those problems that appear most insoluble upon which the inquiring type of mind loves to linger and spend its energies, and, although the problems never may be solved, the misty solitudes to which they lead are glorious and the fitful gleams of half-sunshine that come through are more kindling to the senses of such men, than the brightest sunshine on the barest of hills. It is here, and in such quests, that the biggest of human discoveries are made, and not all of them are in natural science alone.

The search after the mystery and origin of life had profound influence in raising man from a savage to a civilised human being, and is found as an integral part in all religions above a certain level of savagery. Much of the system of morals and ethics of civilised nations is unconsciously grouped round this problem, and we owe the existence of that social conscience which makes each of us our race's keeper to our interest in the nature of life, and our ties with other lives. Leave such a problem alone and attend to routine researches! Why, the human intellect cannot do it, such problems compel attention! What, it may be asked, was it that started all this routine research in biology, in favour of which we are asked to abandon the search after the origin of life? The routine research would not exist, but for a discovery made in investigating whether life originated in a certain alleged way.

If the whole science of bacteriology emerged from a proof that a certain alley did not lead to the origin of life, how much more glorious may that knowledge become that finally leads us to this goal, or even one step onward in our true path towards it. The search after the origin of life is an experimental inquiry, it leads straight to research, that is all the physicist or chemist demands of a theory; it should be enough for the biologist. We who search for this are not occultists, whatever may be said of those who oppose.

Let us then learn to have a catholic spirit about research, and try to convince the world that it commands devotion, not merely because of material advantages which it may bring, but because it is the most lovely and most holy thing that has been given to man. So may we clear the fair name of science of the false charge of materialism that is so often brought against it by those who do not know and judge science purely by mechanical inventions.

Next let us consider the applications of scientific discovery and see if we cherish aright the gifts of the fairy godmother, for her gifts are dangerous if wrongly used. Consider, if this be doubted, the enormous advantages given by mechanical and chemical contrivances in producing the material comforts necessary to civilised human existence, and then turn your eyes to the reeking slums of our great cities. It is clear that natural science cannot go on successfully alone, it must take sociology with it if our world is to be a better world to live in because of the gifts brought by scientific discovery.

Nor is the ideal and the outlook different in the least from that given above for pure research, when we come to consider its applications, the same high spirit must prevail in all our endeavours, or we shall defeat our own ends and miserably fail. Selfishness here, as everywhere, must recoil on the culprit, who only deadens his own soul. Health is needed not to grow wealthy or to prolong to greater length a "lingering death," as Plato puts it, but to fill life with happiness, and beckon the bold and adventurous forward to higher things. Here we must copy nature's own plan and take care of the race as a whole instead of spending our energies upon single individuals or favoured classes. Nor need anyone fear that any individual or any particular class in the community is going to suffer from the adoption of the true scientific attitude towards disease. The penalty taken by nature on the more comfortable classes who have hitherto enjoyed the greater share in government for allowing the existence of poverty, disease, and slumdom, is to utilise this neglected area as a culture-ground for diseases, which invade the classes above. Nature is still at work creating, still conducting evolution at the highest level, and disease is at present the tool with which she is working. So long as those poverty-stricken slums are allowed to remain, just so long is she grimly prepared to take her toll of death and suffering from those who ought to know how to lead on and do it not. The disease and the crime below are to the social community what pain is to the individual, and just as the special senses become more highly organised and sensitive as the nervous system becomes more highly developed, so as the civilisation of the community intensifies does the public conscience awaken to forms of mischief and crime in one generation that were unsuspected in a previous one. So social evils become intolerable and finally are removed. How then are we employing our knowledge as to the causation of disease to the public problem of its removal or abatement?

In regard to the physical environment much has been done during the past generation towards applying the laws of hygiene, as is shown in the sanitation of our great cities, and especially in regard to the question of water-supply. It is good, for example, that Glasgow goes to Loch Katrine for her water-supply, Manchester to the English lakes, and Liverpool to the Welsh hills. Each of these great cities carries for many miles the pure distillate of the hills to its million of inhabitants. It has cost much in pounds sterling, though not more than if each family had a pump in its backyard. On the other hand, think of the disease and suffering and death prevented, enteric fever almost gone where thousands would have died of it, and tens of thousands been debilitated, and these of the best of the citizens, for disease is no eliminator of the unfit. Think of all this, and then say, Did it not pay these great cities to bring the pure water from the lakes in the hills?

But why do these good cities content themselves to allow their little children at a most susceptible age to be supplied still with milk which contains the bacillus of tuberculosis in so large a percentage as 5 to 10 per cent.? And why does the law of the land prevent these corporations from searching out tubercular cows in all the areas supplying them with milk? If it is part of the business of a municipality to see that its citizens have a pure water-supply, why should it not also be allowed to see that they have a clean milk-supply?

Long ago the power to make the lame to walk was regarded as a divine gift. When is mankind going to awake to the fact that science has placed this gift in its hands? Much more than half of the lame and spinally-deformed children in our midst are in that condition because of infection of joints or spine with the bacillus of tuberculosis. By open-air hospitals and open-air schools we seek and succeed in curing a per-

centage of them, but how much better it would be if we took the fundamental problem of tubercular infection in hand and prevented them from becoming lame and deformed.

There is at present on foot in England a great scheme to enable the blind to read, and it deserves our support because it is our fault that these people are blind. The sad fate of the man born blind appeals to all kind hearts; but men are not born blind, they become blind within a week or two of birth because of an infectious disease contracted from the mother at birth. Science knows and has taught the world how this blindness can be quite prevented, and it is because of our faulty organisation for attending to maternities amongst the poor that these people are blind. By proper organisation practically all blindness arising at the time of birth can be prevented. Why is it not done? Thus our modern science can make the blind to see and the lame to walk, but it is so manacled by ancient ways and customs that it is left powerless, and so there are these maimed and darkened lives of innocent people, and they are left partially burdening the community which has only its own folly to blame for the whole stupid position.

Let us consider lastly a disease which collects the last toll from one-seventh of humanity, and debilitates and enfeebles the lives of many whom it does not entirely destroy. At all ages, in infancy, in the prime of life, and in life's decline, it snatches away the best of our fellow-men. How are we organising our campaign against tuberculosis? Bacteriology has taught us that it is an infectious disease and has isolated the organism. It is an undoubted fact, proven to the hilt by many inquiries and observations, that infection passes from individual to individual. How is this knowledge being applied, and how are we attempting to stem the tide of infection? In the United Kingdom alone about 70,000 persons die annually of the disease, and all over the civilised world the total death-roll of human kind annually from tuberculosis probably does not fall short of a million souls. This tide of infection is kept up, year in, year out, and every 70,000 dying annually in Britain must have infected 70,000 fresh victims before they themselves are carried away. Can it not be stopped, this foul tide of infection? What is being done to stop it? Sanatoria are being provided for the early cases, the bad and most infectious cases are largely being left alone to sow infection broadcast and then die. This is the chief means being used at present to stop the tide. The early non-infectious case is deemed the more important to look after, and the well-advanced, open, thoroughly infectious case is left to itself to infect others and then to die. This is the condition of our public health attitude in regard to tuberculosis. It is a travesty on the application of all biological laws, and in direct opposition to all laws of racial preservation. Industrial conditions have produced an artificial environment and enhanced the chances of infection by the organism of this disease; it should be our plan to copy nature's method and safeguard the interests of the community, and to do this we must proceed on the plan of separating the source of infection—that is to say, the infectious individual from the sound individual. This is done with success in the case of smallpox and cholera, and this plan has eradicated hydrophobia; why should it not be carried out in the case of tuberculosis? Under present conditions men, women, and children are going on unwittingly infecting one another by the thousand with tuberculosis in school, workshop, and home, and we who know it take no public action and raise no clamant outcry against it. It is of more value to the community to isolate one pauper far advanced in tuberculosis than to send ten early cases to sanatoria. This disease must be stopped at its source as well as dealt with on its course. No disease has ever been eradicated from a community by discovering cures for it, and none ever will; many diseases have disappeared because their sources have been cut off.

Let us be scientific, let us search out the truth; having found it, let us act upon it, and let us conceal nothing that is true.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—In consequence of the conversion of the new buildings at Edgbaston into a base hospital during the war, arrangements are being made whereby as much as possible of the work usually carried on there will be continued in Mason College and the Municipal Technical School. Unfortunately, some of the laboratory work will have to be curtailed, and much research work will be suspended.

The hostel for women students is at present used to accommodate the nursing staff of the hospital, but arrangements are being made to provide temporary quarters for the evicted students in a private house in Edgbaston.

The following notice of resolutions passed by the council on September 4 has been issued by the Vice-Chancellor:—(1) That the University will, so far as possible, continue its work for the benefit of those students who are prevented from undertaking active service in the Army or Navy, but that the University's advice to members of the staff, students, laboratory, and other assistants, and college servants, who are of suitable age and physically fit, is that they should enlist and serve their country. That students who propose to enlist should consult the Vice-Principal or the dean of the faculty of medicine, and (if minors) should obtain the written consent of their parents or guardians before sending in their applications. (2) That with a view of encouraging enlistment, the University undertakes to allow leave of absence to any of the above-mentioned persons during their naval or military service; that they be reinstated on their return with no loss of position or emoluments consequent on their enforced absence; that the council pay them (or such other person or persons as they may appoint) such sums as with the pay and allowances they receive from the Government will make up their full salary or wages; and that students shall be entitled to postpone any scholarships or other aids which they may hold, and, where possible, may be allowed to shorten the time of attendance at lectures necessary for a degree, without, however, the remission of any essential requirements in respect of examinations prescribed for their course.

Mr. L. J. Goldsworthy has been appointed professor of chemistry at the Victoria College of Science, Nagpur.

Dr. D. Waterston, professor of anatomy in King's College, London, has been appointed to succeed Prof. J. Musgrove as Bute professor of anatomy, University of St. Andrews.

Four Gresham Lectures on heredity will be delivered on October 6, 7, 8, and 9, by Dr. F. M. Sandwith, at Gresham College, Basinghall Street, E.C. The lectures are free to the public, and will begin each evening at six o'clock.

The Merchant Venturers of Bristol have decided to offer to engineering students of Belgian universities,

or of the University of Lille, free places in the faculty of engineering of the University of Bristol, which is provided and maintained in their college. Of course, many of these students are at present serving with the respective armies, but it is hoped that any students who were unable to serve and who are, at present, in England will avail themselves of this offer.

The new session of the Sir John Cass Technical Institute, Aldgate, E.C., which is especially devoted to technical training in experimental science and in the artistic crafts, will commence on Monday, September 21. The instruction in experimental science provides systematic courses in mathematics, physics, and chemistry for London University examinations, in addition to the courses on higher technological instruction, which form a special feature of the work of the Institute. In connection with the latter, several new departures are being made for the coming session. The curriculum in connection with the fermentation industries has been much developed and now includes courses of instruction on brewing and malting, bottling and cellar management, brewery plant, and on the micro-biology of the fermentation industries. A connected series of lectures dealing with the supply and control of power has also been arranged to meet the requirements of those engaged in works connected with chemical, electrical, and the fermentation industries. In the department of physics and mathematics a special course of lectures and demonstrations will be given on colloids, which will deal with the methods employed in their investigation and their relation to technical problems; also special courses of lectures on the influence of surface-tension on chemical phenomena, and on the construction and uses of physical instruments in their application to physical chemistry, on the methods of differential and integral calculus, and on the theory and applications of mathematical statistics, the latter of which will treat of the application and modern mathematical methods of dealing with statistical data in social, educational, economic, and physical problems. In the metallurgy department, in addition to the ordinary courses of instruction in general metallurgy, special courses of an advanced character are provided on gold, silver, and allied metals, on iron and steel, on metallography and pyrometry, on heat treatment of iron and steel, on mechanical testing of metals and alloys, on mining, mine surveying, and on mineralogy.

The director of technical instruction in the Transvaal, at a conference held in Pretoria in November, 1913, on technical, industrial, and commercial education, has made a thoughtful contribution on technical education as it affects the training of the boy for industry ("The Trades School in the Transvaal." By W. J. Horne. *South African Journal of Science*, August, 1914). Naturally he deals with the peculiar conditions of industry in South Africa, having regard to the large employment of native labour, the special and sporadic character of the industries and the large use of automatic machinery. Whilst expressing the belief "that human nature can be ennobled by the organisation of industry in the service of education," the author deals rather with the training of the boy outside the industry, and attempts to show the possibilities of preparing him from quite an early age for some specific craft chosen as his future occupation. The type of school advocated is an apprenticeship school in which the boy is kept at work, including short breaks, for forty-seven hours a week, of which considerably more than half is workshop practice. The course extends over forty-eight weeks of the year, and is continued for three and a half years, payment being made to the pupil ranging from 8*d*. to 1*s*. 9*d*. per diem according as the pupil is graded. Little is done to ensure the general cultivation of all the child's faculties. He is regarded as the human factor in the industrial machine; only utilitarian ends are sought; not his own uses, but the uses of an industrial society are the aim. The employer is not regarded as having responsibility for the training of his employés. He must have them ready trained or simply as labourers. The author reviews the position of the trades school, in which theory and practice are taught—the industrial school exclusively practical—the manual training school which provides for the due training of all the child's faculties irrespective of future calling. The policy and methods of the trades school as here advocated will scarcely commend themselves to thoughtful British educationists.

The new session of the Battersea Polytechnic opened on Tuesday, September 15, and particulars of all the courses and classes are given in the calendar of the Polytechnic. The following sections of the work are deserving of special notice: Full-day and evening courses in preparation for the intermediate and final degree examinations in science, engineering, and music are offered. In the day technical college full-time courses are arranged in mechanical, civil, electrical and motor engineering, architecture and building, chemical engineering and art, the courses covering a period of three or four years, at the end of which time students passing the necessary examinations are awarded the Polytechnic diploma. There are also full university and diploma courses in mathematics, physics, chemistry, botany, etc. Concurrently with the diploma courses, students can prepare for and take the degree examinations in science and engineering of the University of London. The training department of domestic science offers two-, three- or four-year courses in preparation for the teachers' diploma in domestic subjects, and the commerce department gives a course extending over two or three years in preparation for civil service and other examinations, and for secretarial and general business appointments. The physical training department for women offers a course extending over three years, and prepares students for posts as teachers of physical training, drill, gymnastics and games. The department of hygiene and physiology, which is housed in the fine block of buildings recently presented by the Drapers' Company, provides complete and comprehensive courses in the following sections: combined course of training for women sanitary inspectors and health visitors, courses for the higher and lower certificates in hygiene, and the course for the lower certificate in physiology. In view of the increasing attention which is being paid to the health and welfare of the community, this department has a wide and ever-growing sphere of usefulness before it.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, August 31.—M. P. Appell in the chair.—G. **Bigourdan**: Observation of the eclipse of the sun of August 21, 1914. The times of the commencement and end of the eclipse were observed under unfavourable conditions.—E. **Vallier**: Internal ballistics. Various formulæ from the recent work of N. Zaboudski. Experiments on the gas pressures and projectile velocities in 3-in. (76·2 mm.) cannon. Approximate formulæ are deduced for the velocities and pressures as functions of the weight of the explosive, weight of the projectile, length of the powder cham-

ber, and thickness of the band of explosive.—Kr. **Birkeland** and M. **Skolem**: Calculation of the lines of equal intensity in the zodiacal light, on the supposition that it arises from the light diffused by a nebula of electrons or of radiant matter of solar origin. The formulæ deduced are illustrated graphically in seven diagrams.—H. **Bourget**: Partial eclipse of the sun of August 21 observed at the Observatory of Marseilles. The first and second contacts were observed under good conditions.—D. **Saint-Blancat** and L. **Montangerand**: Observation of the partial eclipse of the sun of August 21, 1914, at the Observatory of Toulouse. The times of first and second contacts are given.—I. **Tarazona** and V. **Marti**: Observation of the eclipse of the sun of August 20–21, 1914, made at the astronomical observatory of the University of Valentia (Spain).—J. J. **Landerer**: The total eclipse of the sun of August 20–21, 1914.—L. **Bouchet**: New determinations of Poisson's coefficient for vulcanised india-rubber. The pressures were produced by electrostatic means. The value found for Poisson's coefficient was appreciably equal to 0·5, signifying that india-rubber is incompressible.

(1) MR. LEITH'S book does not cover so wide a field as Prof. James Geikie's "Structural and Field Geology," which was reviewed in this journal in 1912 (vol. xc., p. 159), nor is it so attractive at first reading as Prof. Wilckens's "Grundzüge der tektonischen Geologie" (NATURE, vol. xcii., p. 564). But it represents the application of close thinking to the problems of earth-fracture and the displacement of rock-masses in regard to one another, and it forms a specialised manual for the student of all kinds of rock-flow. The large amount of sliding and differential movement that takes place between layers of the same contorted series may be well realised in the field; but it is not apparent in our ordinary diagrams. Mr. Leith, on p. 114 and elsewhere, very usefully directs attention to it, and connects the "drag-folds" seen on a small scale with the overfolded structure of the Alps. Willis's terms, "competent" and "incompetent," which are too familiar in their ordinary usage, are adopted (p. 111) for layers of rock that respectively resist and yield to compound crumpling. A fold may exhibit "competence" up to a certain point, and may become "incompetent" on continuance of pressure, yielding in this case as a series of folds in which the successive beds are similarly curved. The book is full of matter that leads to accurate realisation, and includes useful reviews of such widely separated terminals of the subject as the origin of joints and the theory of isostasy.

(2) In his description of North-west Saxony, Dr. E. Krenkel has the advantage of dealing with a district that includes a palæozoic range folded in Middle Carboniferous times, a conspicuous development of Permian strata with associated volcanic rocks, Oligocene and Miocene brown coals, and boulder-clay in which Scandinavian granite (rappakiwi) has been found. The combination is a happy one for those who study geology at Leipzig, though there is a large gap in the stratigraphical succession. The glacial and fluvioglacial deposits contain the mammoth, *Rhinoceros mercki*, and the reindeer. Ice-scratched surfaces are noted at several points, and the dry epoch at the close of the last ice-age has left its traces in the form of grooves etched by wind-borne sand on the porphyry cliffs of the Klein Berg (p. 91). The contact-metamorphism due to granite of Carboniferous age is studied in the last of the excursions, and the question is left open as to whether the associated gneisses are a marginal type of the granite, or an older mass into which the latter has intruded (p. 180).

(3) The early association of Mr. F. Chapman, now of the National Museum, Melbourne, with the detailed researches of Prof. Rupert Jones gave promise of the accurate contributions that he has made to Australian palæontology. It is an admirable sign of the times that Great Britain is no longer the field to which problems of the southern hemisphere must be referred. The publication of an introduction to the study of fossils in which Australian examples are primarily employed cannot fail to stimulate observation, and such absorbing details as the "Collyweston Slate" and the "Oldhaven Beds" may in time drop out of view in examination papers set for our antipodes. At the same time, the author will be the first to recognise that notable gaps in the record must be filled in by reference to other lands. The Triassic cephalopods and almost all fossil mammalia serve as notable examples, and a "students' manual of palæontology" may be expected to lay a broader foundation than is here given. Mr. Chapman's book, however, is justified by its principal title, and it will be of immense help to workers in Europe who require a ready reference to species recognised on the other side of the equator. The bibliographies following each chapter still further deserve our gratitude.

(4) Mr. McLeod's book is bound for the pocket, and contains useful hints for the prospector, who is shown how to perform a number of tests with ingenious and simple apparatus. It is, however, taken for granted that he will not be interested in the reactions involved. The chemical composition of minerals is loosely stated, and a mixed list of minerals and chemical oxides on p. 81 is styled a list of "ores." The mouth-blowpipe is not relied on; yet it would reduce cassiterite in

a tenth of the time occupied by the method given on p. 37, while a candle is often easier to deal with in experiments requiring heat than the "brisk wood fire" advocated on p. 23. We should like a prospector to take up this practical little book after an elementary course in mineralogy; but this seems too much to ask of those whose energy and observation may affect the fortunes of huge companies. G. A. J. C.

INSECTS AND DISEASE.

A Text-book of Medical Entomology. By Dr. W. S. Patton and Dr. F. W. Cragg. Pp. xxxiv+768+lxxxix plates. (London and Madras: The Christian Literature Society for India, 1913.) Price 15.12 rupees, or *1l. 1s.*

THE vast literature which has sprung up in connection with medical entomology gives some indication of the importance of this comparatively new subject, and the work under review is the first attempt at a text-book. The subject chiefly concerns those medical and veterinary officers practising in the tropics, frequently out of the reach of current literature, and this book is designed to give to these men a concise introduction to entomology in so far as it is connected with medicine.

The book is divided into twelve chapters, and of these the first four, occupying rather more than half the volume, deal with flies. The blood-sucking and other noxious types of these insects are dealt with very fully, and chapter ii., which is entitled "Anatomy and Physiology of the Blood-sucking Diptera," is perhaps the best in the book. The different types of "biting" flies are discussed as to general structure and internal anatomy, and the question of the origin of the mouth-parts of the "biting" from the "non-biting" Muscidæ is made an excuse for bringing in an excellent description of the mouth-parts of the house-fly.

Chapters v. to x. deal with fleas, bugs, lice, ticks, mites, and the pentastomids or "tongue worms," the latter two groups, although not insects, being usually regarded as coming within the meaning of the term "entomology."

The book is well illustrated, there being eighty-nine plates, the majority of the figures being original sketches by the wife of one of the authors, and many of these indicate a large amount of careful dissection.

There are a few mistakes, such as that in bugs the "mandibles are so opposed as to form a channel with a circular lumen, while the maxillæ are armed with cutting teeth" (p. 6), and there are occasionally definite statements made upon debatable points, as with regard to the number of segments composing the insect head (pp. 9 and 13); but the chief complaint we have to make is against the way the book has been edited. There are, for instance, some sentences which are either difficult to understand or altogether unintelligible. Thus, on p. 7 we read, "In the Diptera . . . the sucking tube is formed by the outgrowth from the pharynx of two spatulate slips, one dorsal and the other ventral," and it is not until p. 21 that we find the real meaning of this extraordinary statement, where it is said, "In the Diptera [the adaptation of the mouth for sucking] is accomplished by the development to a very high degree of just those parts of the mouth apparatus which are rudimentary in the cockroach, namely, the epipharynx and the hypopharynx. These are outgrowths from the dorsal and ventral walls respectively of the stomodæum. . . ."

On p. 15 is the cryptic statement: "When the head [of a fly] is viewed from behind the whole of the posterior wall is seen to be chitinous, while at the lower border there is a rounded foramen between the anterior and posterior surfaces through which the proboscis is protruded."

Again, in various places we find references to earlier passages which it is almost impossible to trace. Thus, on p. 130, "The relations of the hæmatocœle of the proboscis of the fly have been described at some length in connection with the mechanism of the mouth-parts." But there is no section entitled "Mechanism of the mouth-parts"! There is a heading "Mechanism of the proboscis," but the required statement is not there, and it is only from three words in one sentence that one gets a hint, and we ultimately find what we want under "Movements of the Labella" in connection with a description of the proboscis of Musca (p. 46).

One other complaint we make with regard to the difficulty of using the book. In a number of cases there is much lettering on the plates, and there is the greatest difficulty in finding the explanatory pages. There is a page of reference letters to cover plates i. to vii. immediately following plate i. and just before plate viii. is a page to cover plates viii. to xiii, but there is nothing on any of the plates to indicate where the explanatory pages are to be found. Unfortunately also the page of reference letters for plates i. to vii. is almost wholly wrong.

There are thus many faults in the book, and they are the more to be regretted since much of the material is really first-class. It can only be hoped that the work will run to a second edition in which these defects can be remedied.

FRANK BALFOUR BROWNE.

THE INIMITABLE OBSERVER.

Fabre, Poet of Science. By Dr. C. V. Legros. With a Preface by J. H. Fabre. Translated by Bernard Miall. Pp. 352. (London and Leipzig: T. Fisher Unwin, n.d.) Price 10s. net.

The Life of the Fly. With which are interspersed some Chapters of Autobiography. By J. Henri Fabre. Translated by A. T. de Mattos. Pp. xi+508. (London: Hodder and Stoughton, n.d.) Price 6s. net.

MANY who have enjoyed Fabre's entomological studies will be glad to have an opportunity of knowing the author more intimately, and we have to thank Dr. Legros for a fascinating biography and appreciation, which has been admirably translated by Mr. Bernard Miall. Jean-Henri Fabre was born at Saint-Léons, in the canton of Vezins, in 1823, some seven years earlier than Mistral. From his childhood he was a lover of nature and poetry, and though he was brought up amid the rudest privations, they did not freeze "the genial current of his soul." As a school-teacher at Carpentras, with 28*l*. a year, often in arrears, he continued his own education, and all was grist that came to his mill. He had an enthusiasm for knowledge—about plants, rocks, coins, mathematics, chemistry, physics, and what not. When he attained his majority he had the courage to marry. A period in Corsica, as a teacher of physics, was marked by a revived enthusiasm for mathematics, and by meeting Moquin-Tandon, who initiated him in the discipline of dissection. The next period was at the Lycée of Avignon; and it was there, in 1854, that a volume by Léon Dufour, then "the patriarch of entomologists," decided his vocation. In spite of having to work excessively hard to keep the family table spread, and in spite of every possible discouragement, Fabre produced in a few years a series of studies which made his reputation among entomologists. As early as 1859 Darwin spoke of him as "that inimitable observer."

There can be no doubt that Fabre's life was terribly severe. An observer of the first rank had to eke out a miserable salary with "abominable private lessons" which spoiled his temper and wasted his energies. His discovery of a profitable way of extracting the pigment of madder was snatched from his hands, and his dream of freedom to follow his vocation faded away. His free popular lectures at the Abbey of Saint-Martial at Avignon are said to have been famous for a generation, but it is more certain that they aroused jealousy and ill-feeling. He was turned out of his house, and might have come entirely to grief had it not been for the kindness of John Stuart Mill, who was then residing at Avignon. After twenty ill-rewarded years of service, Fabre shook off his yoke and retired in 1871 to Orange. He kept things going in a precarious hand-to-mouth fashion by writing introductions to the various sciences, which had a great vogue in their day, and had certainly the great merit of teaching much in a heuristic fashion with the simplest possible apparatus. But Fabre's fine work was ill-paid; the keepership of the Requen Museum at Avignon was taken from him; he lost a son of great promise; he had a very serious illness; his cup of bitterness was full. When his landlord at Orange lopped the double row of plane-trees which formed an avenue before his house, he could endure towns no longer, and retired to the peaceful obscurity of Sérignan—"a quiet corner of the earth which had henceforth all his heart and soul in keeping."

In his hermit's retreat, living an ascetic life, Fabre gave himself up to observation and reflection, and produced the well-known studies—at once poetic and scientific—that fill the ten volumes of the "Souvenirs Entomologiques." After forty years of desperate struggle he had won for himself freedom, and he used it nobly. "For thirty years he never emerged from his horizon of mountains and his garden of shingle; he lived wholly absorbed in domestic affections and the tasks of a naturalist." He remained extremely, sometimes painfully, poor, and was often worried; but he made a big success of his life, and if he has had many hardships and sorrows he has found in the *vis medicatrix Naturae* much more than healing. His wide scientific interests and culture made him an all-round naturalist; his genius as an observer, not equalled since Réaumur, brought him into extraordinarily intimate acquaintance with the objects of his study; his indefinable sympathy helped him in tracking the mysterious paths of instinctive behaviour. It need not be supposed that he has been without exception accurate, for he has sometimes read too much of the man into the beast; but what eyes the man has had! It cannot be maintained that his judgment has always been sound—witness his dogged anti-evolutionism—but there have been few naturalists who have got so near the intuition of life. We would pay homage to the veteran; he has peaceful satisfaction in the twilight of his days for he knows that he has the gratitude of all who love nature.

A good sample of Fabre's essays will be found in the selections from the "Souvenirs Entomologiques" which have been excellently translated by A. Teixeira de Mattos and published under a somewhat inaccurate title, "The Life of the Fly."

The Life of Flies would have been nearer the mark, for most of the essays deal with Diptera. There are others, *e.g.* on pond-life, caddis-worms, insects and mushrooms, which have not much to do with flies, and the interspersing of biographical chapters—charming as they are—removes the book even further from being a unity. The essays, like everything Fabre wrote, are vividly interesting; they discover to us the wonder of life; they set us thinking; they make us wish to go out and observe. The now well-known style suffers necessarily in translation, but it is extraordinarily picturesque and arresting. We confess to getting wearied when the conversationalism and anthropomorphism is too prolonged; but it is marvellously fine. "I pry into life," Fabre said, and these essays give us some idea of his reward. As the translator has done his work well, and will doubtless do more, may we suggest that the repeated wrong use of the term "species" in the notes is irritating, that starfishes cannot be included in the modern use of the word zoophytes, that the natterjack "sometimes as large as a plate," excites remark; and so does "underneath, in a pool of sanies, is a surging mass of swarming sterns and pointed heads. . . ."

AN ITALIAN TEXT-BOOK OF METALLOGRAPHY.

Le Leghe Metalliche ed i Principii Scientifici della Metallografia Moderna. By Prof. Domenico Mazzotto. Pp. xi+421. (Modena: G. T. Vincenzi e Nipoti, 1913.) Price 6 lire.

PROF. MAZZOTTO'S work is the first complete treatise on metallography in the Italian language. It is very similar in scope to other text-books which deal with the chemical rather than the engineering aspect of the subject, and the treatment is throughout mainly theoretical. As might be expected from the nature of the author's original publications, the quantitative interpretation of the equilibrium diagram receives much attention, and the student will find in these chapters a useful review of the possible types of equilibrium amongst alloys. The ternary and quaternary systems, which have been studied chiefly by Italian metallographers, are also described with the aid of diagrams.

This theoretical section is followed by the discussion of a limited number of actual systems, and this part of the work is somewhat less satisfactory. A more critical treatment of the experimental material would have been of great advantage, as several systems are represented by diagrams taken from early investigations, which later researches have shown to be incorrect. The copper-manganese series is a conspicuous example, the maximum in the second diagram being due to the presence of carbon in the materials employed by Wologdine.

Practical methods are only briefly described, but the usual methods of taking cooling curves are illustrated and explained. Several forms of pyrometer are included, however, which are useless for metallographic work, being designed only for the approximate measurement of furnace temperatures in works practice. Microscopical methods occupy only a few pages, but some photo-micrographs are reproduced from well-known sources.

The general sections on physical and mechanical properties, and on the modes of formation of alloys, although brief, are well written, and should serve as an interesting introduction to the subject for students previously unacquainted with it. The impression of metallography which such students will obtain is somewhat one-sided, but the science is new in Italy, and the admirable work which has been done already by such investigators as Bruni, Giolitti, Parravano, and Mazzotto is a guarantee that it will become firmly established there. By the time the author is called on to revise the present book, his attention will probably have been directed to those aspects of the subject which are now unrepresented, and it will be possible, by reducing the disproportion between the several parts, to render an excellent introductory text-book still more valuable.

C. H. D.

OUR BOOKSHELF.

A Practical Treatise on Sub-aqueous Foundations. Including the Coffer-Dam Process for Piers, and Dredges and Dredging, with numerous Practical Examples from Actual Work. By C. E. Fowler. Third edition, revised and enlarged. Pp. xliii+814. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 31*s*. 6*d*. net.

THIS book first appeared in 1898 under the title "The Coffer-Dam Process for Piers." The title was altered in 1904 to "Ordinary Foundations, including the Coffer-Dam Process for Piers." The work now presented under the title given above contains a large amount of new matter, consisting of practical examples of work, much of which has been constructed by the author, or with which he has come in intimate contact in a consulting capacity. Among the new subjects treated may be noted concrete piles, the jetting of piers, metal sheet-piling, the open-dredging process, caisson work and caisson disease, diving, the bearing power of soils.

An attempt has been made to render the book so complete that the engineer may find it un-

necessary to consult other volumes in order to obtain information regarding the subjects covered. We are afraid that this claim is too wide. The engineer will find a great deal of information of a practical character in the volume, together with methods of calculation (often short cuts) which will enable him to carry through his designs, but to understand completely what he is doing he will certainly either have to possess other knowledge or consult other books. For example, in the section dealing with the calculations of piers, footings and retaining walls, earthwork problems are treated sometimes by the wedge theory, elsewhere by Rankine's theory, and again with friction allowance on the wall. Attention is not directed to the differences of these methods. The treatment of the pressures on the base of the wall is not at all clear, and will leave the engineer who uses the method given in a state of uncertainty as to what he has really done.

Principles of Metallurgy. By A. H. Hiorns. Second edition. Pp. xiv + 389. (London: Macmillan and Co., Ltd., 1914.) Price 6*s*.

IT is almost twenty years since the first edition of this book appeared. During that time metallurgy has advanced very rapidly, and any new book or new edition which is published should have many novel features to indicate.

The present volume reviews briefly the principal metallurgical phenomena and extraction processes and forms one of a series by the author. It is a work which is intended for use in a technical school and for the instruction of apprentices and other workers engaged in the metal industries and whose employment demands some elementary knowledge of metals, their properties, and methods of production.

As a consequence of attempting to cover the whole field of metallurgy in some 370 pages, the author has treated several sections rather scantily, while others are out of proportion to their importance. Thus, in the paragraph on the Bessemerisation of copper, no discussion is given of the true function of the furnace lining, and although a "more or less basic" lining is mentioned, no stress is laid upon the recent adoption of basic-lined converters. It is noticeable, too, that the author occupies twelve pages in descriptions of various, almost obsolete, chlorination processes for the treatment of gold ores, whereas he dismisses the more important cyanide process in three pages.

The work is suitable to place in the hands of a young student on his earliest venture into the domains of metallurgy, but he would be well advised to pass, at an early stage, to the larger treatises on the subject. W. A. C. NEWMAN.

Gearing: a Practical Treatise. By A. E. Ingham. Pp. xi + 181. (London: Methuen and Co., Ltd., 1914.) Price 5*s*. net.

THE object of this volume is to present in a simple manner the general scientific principles which underlie the subject, and to give particulars of the most approved methods of solving problems connected with various forms of gears. Spur, bevel, worm, spiral and helical gears are included, and methods of cutting these gears are explained and illustrated by photographs. The calculations given are of the simplest possible character and should present no difficulty to anyone who knows ordinary arithmetic. Extensive tables are given which will simplify the process of finding the pitch, diameter, and outside diameter of wheels having a given circular pitch. A considerable amount of space is taken up with blacked drawings showing the comparative sizes of teeth having progressive diametral and circular pitches. The latter might have been omitted, and space found for a discussion of the new problems introduced by the applications of helical wheels in marine turbine speed-reduction gears. The desire of the author to keep the matter treated within the limits of simplicity prescribed by the knowledge of the readers he has in view no doubt accounts for the many omissions in an otherwise useful volume.

Historical Sketches of Old Charing: The Hospital and Chapel of Saint Mary Roncevall; Eleanor of Castile, Queen of England, and the Monuments erected in Her Memory. By Dr. J. Galloway. Pp. 82. (London: John Bale, Sons, and Danielsson, Ltd., 1914.) Price 10*s*. 6*d*. net.

THESE studies in the history of Old London, by the senior physician and vice-president of Charing Cross Hospital, originally published in the hospital *Gazette*, and reprinted for the benefit of that institution, form a useful contribution to local history. The first part contains an account of the hospital and chapel of St. Mary Roncevall at Charing Cross, a branch house of the great convent at Ronesvalles in the western Pyrenees. The London convent owed its foundation to the liberality of William Marshall, Earl of Pembroke, eldest son of the great William Marshall, Protector of the King and his kingdom after the death of John. It enjoyed a long career of prosperity and usefulness until its final dissolution by Henry VIII. in 1544. On the site was built Northumberland House, purchased by the Metropolitan Board of Works in 1874, and now occupied by Northumberland Avenue and the great buildings which flank that thoroughfare.

The second part of the book is an account of the monuments erected to commemorate the death of Queen Eleanor, and the removal of her remains from Harby, near Lincoln, where she died in 1290, to Westminster Abbey. These consist of her tomb in the Abbey, the work of Richard Crandale, and the series of beautiful crosses, of which those at Chepe, Charing (the site now occupied by the statue of Charles I.) Grantham, Stamford, Stony Stratford, Woburn, Dunstable, and St. Albans, have disappeared, while those at Geddington, Northampton, and Waltham survive in a more or less perfect condition. The preparation of this book, with its fine illustrations and copious references to original authorities, was obviously a labour of love, and it forms an interesting addition to the great library of books on Old London.

Kinship and Social Organisation. By Dr. W. H. R. Rivers. Pp. v+96. (London: Constable and Co., Ltd., 1914.) Price 2s. 6d. net.

DR. RIVERS has made a speciality of the adaptation of the genealogical method to the interpretation of social facts, to which he has devoted much knowledge and hard thinking. In the present collection of lectures delivered at the London School of Economics he uses his special studies of social life in Melanesia to a consideration of the classificatory system, the essential feature of which is the application of its terms, not to single individual persons, but to classes of relatives which may often be very large. The discovery of this system was the work of Lewis Morgan, who, diverting his attention from the facts at his disposal, attempted to formulate a condition of general promiscuity developing into group marriage, a view offensive to his readers and certain to meet with active criticism. His first opponent was J. F. McLennan, who urged that the terms used formed merely a code of courtesies and forms of ceremonial address for social intercourse. Another theory, that of Prof. Kroeber, suggested that the use of these forms does not depend upon social causes, but that they were conditioned by causes purely linguistic and psychological.

Dr. Rivers, after a careful analysis of the facts, has little difficulty in disposing of these theories. He shows that the process of determination of the nomenclature of relationship by social conditions has been rigorous and exact; further, that every detail of these systems has been so determined. "Even so small and apparently insignificant a feature as the classing of the sister-in-law with the sister has been found to lead back to a definite social condition arising out of the regulation of marriage and of sexual relations." The lectures form a useful contribution to the study of the history of human marriage.

The Farm Woodlot: a Handbook of Forestry for the Farmer and the Student in Agriculture. By E. G. Cheyney and Prof. J. P. Wentling. Pp. xii+343. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 6s. 6d. net.

THIS is an excellent handbook of elementary forestry, specially adapted for the use of farmers and students of agriculture in North America, yet containing much that should be of interest to landowners in this country. There are well-written chapters on practical sylviculture, on forest mensuration, protection and utilisation, on ornamental planting, and about the durability and preservation of timber. A special article deals with the economic position of the forest and the work of afforestation in the modern State. The authors discuss the question of the apportionment of the soil of a country into the two classes of agricultural and forest lands, on the only just basis; a comparison of the net revenues obtainable from the land under other crops, and under trees. Most of us, who regard the United States as producing timber only from her virgin forests, will learn with surprise that already in New England plantations of white pine have yielded six per cent. annually on the investment.

Another chapter is devoted to the history of the forests of Germany, the United States, and Canada. It is satisfactory to hear that although the progress of scientific forestry in Canada has been slow, and dotted with many set-backs, the prospect at present is promising. In the United States the Forest Service has long been at work, and is now carrying out on the extensive territory under its jurisdiction a magnificent programme, in which the question of profit is never forgotten, all its measures being governed by business principles, none of them by sentiment.

Matriculation Mechanics. By Dr. William Briggs and Prof. G. H. Bryan. Third edition. Pp. viii+363. (London: W. B. Clive, University Tutorial Press, Ltd., 1914.) Price 3s. 6d.

ADVANTAGE has been taken of the publication of a new edition of this well-known class book to add a collection of simple experiments to illustrate the fundamental principles of mechanics. This addition will certainly increase the usefulness of the book.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Renunciation of Honorary Degrees.

I HAPPEN to see in one of the Dutch journals that a number of German men of science have divested themselves of honours bestowed upon them by British universities and learned societies, on account of the war between England and Germany.

Will you allow me to express the hope, by means of this letter, that my British friends will not reciprocate this action by a similar one?

To my mind, worse than the young lives sacrificed, worse than the destruction of ancient monuments of arts and science, is the almost inevitable consequence of this terrible war: the sowing of hatred and distrust between different nations.

Now it is my firm belief that it is the duty and the privilege of scientific men all the world over to do all in their power gradually to allay these feelings of hatred and distrust.

For this reason especially I regret greatly the action of the German "savants," and earnestly pray my British friends to abstain from similar action.

J. P. LOTSY.

Perpetual Secretary of the Dutch Society of Sciences, Haarlem, September 12.

The Green Flash.

As the green flash continues to appear in your columns, may I give some limiting observations. At sea I have always seen it, if the horizon is clear and not too red. It is also well seen over distant mountains in Egypt at rising, when the sky is less red than at setting. The horizon may be as near as two miles, and still show traces of a green edge. At any distance less than five miles the disappearance can be followed up for some seconds by walking up a slope, so as to keep the green edge under continuous observation.

W. M. FLINDERS PETRIE.

The Large Non-Conchoidal Fracture-Surfaces of Early Flint Implements.

WHEN a representative series of flint implements is examined comprising examples of every stage of culture from the Neolithic back to the earliest Chelles-Palæolithic specimens, it will be observed that, generally speaking, the older the implements the less they show small and "dilettante" flaking in their manufacture, and that when the earliest Chelles stage is reached the flints have been fashioned by the removal of large, bold flakes not supplemented by secondary work, such as is to be seen upon nearly all the examples of later cultures.

When a further series of implements is examined which predate the earliest Palæolithic specimens, this peculiarity is seen to be still more marked, the flints in many cases having been fashioned solely by "quartering" blows producing clean, flat fracture-surfaces exhibiting neither well-marked cones of percussion nor conchoidal rippling, such as are so often produced by the more ordinary type of blow. If, as often happened in pre-Palæolithic times, an implement was produced by means of such blows, the flakes would not in the first place exhibit the normal characteristics of human blows, and secondly, many of these flakes would, in the process of manufacturing the implement, of necessity be truncated and their resemblance to accepted "human" flakes made still smaller. Some of these truncated flakes, moreover, at first sight have the appearance of being thermal breaks, and it requires a close and intelligent examination of their surfaces with a high-power lens to discern those small indications which demonstrate that the flakes have been removed by blows. In addition to the cone of percussion and conchoidal rippling which are often produced by a blow upon a flint, *fissures* of varying size are also formed which radiate from the point of impact.

Some of these fissures, which appear to me to represent "tears" made in the flint by the cleaving force of the blow, are very minute, but in nearly every case are capable of discernment with a really good lens. I have found by experiment that the "quartering" blow to which I have referred, though not producing a well-marked cone of percussion, and very frequently no conchoidal rippling, nevertheless gives rise to these small fissures, and that it is generally possible by the evidence they afford to determine the exact "fracturing agent" and the direction in which it has acted.

It seems to me to be necessary for the prehistorian to recognise the real meaning of these peculiar fracture-surfaces of early flint implements, and I think their non-recognition has been the cause of the inability of many observers to accept these specimens as having been humanly fashioned. To those, however, who are familiar with the method of production of such fracture-surfaces it becomes clear that great precision and dexterity are needed to make an implement by means of this particular type of blow, and that in consequence the probability of unguided natural forces having produced them is practically eliminated.

J. REID MOIR.

12 St. Edmund's Road, Ipswich, September 12.

BRITISH AERONAUTICS.[1]

THE fact that methods of experiment and the apparatus used for test have become standardised has rendered it possible to add considerably to the detailed knowledge relating to aeronautics, and the result is reflected in the increased size of the annual volume published by the Advisory Committee for Aeronautics. The amount of test-work still called for is enormous, and for some time to come problems will need to be taken in order of urgency, whilst many problems of great scientific interest are left for later consideration. Amongst such problems may be classed the mathematical investigation of motion such as that illustrated in Fig. 1, which shows a photograph of fluid motion round a model of an aeroplane wing. The photograph had a time-exposure of about one second, and the lines indicate the direction of the flow, and their length the mean velocity. So far no promising hydrodynamical analysis has been found for such a flow.

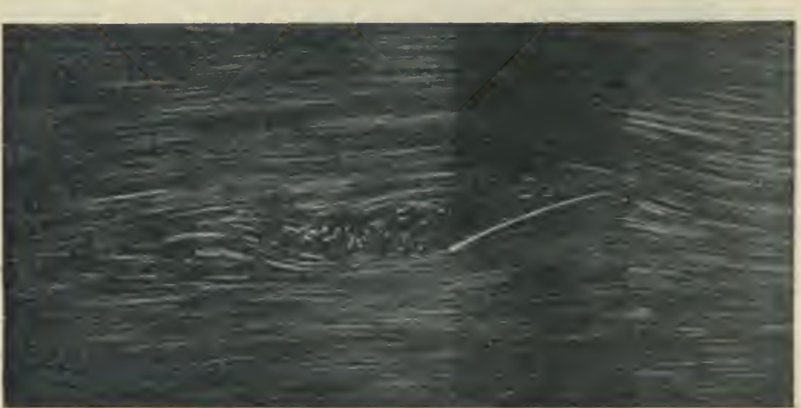

FIG. 1.—Flow round aerofoil inclined at 16°. From "Technical Report of the Advisory Committee for Aeronautics for the Year 1912–13." By permission of the Controller of H.M. Stationery Office.

The report deals with quite different subjects, and relates almost entirely to the experimental determination of the forces and couples acting on models immersed in a moving fluid. A considerable range is covered in relation to parts of aeroplanes, and it is now possible to make a good prediction of the resistance of a new flying machine from the resistances of its component parts. One section of the report shows how model results are applied to full-scale work at the Royal Aircraft Factory.

The report is concerned, on the model side, almost entirely with results obtained in the new four-foot channel at the National Physical Laboratory. The original channel, although very useful, was not considered to be satisfactory apparatus for the permanent equipment, and a series of experiments on model channels and buildings was undertaken in order to find, if possible, some design for a channel which would lead to improved steadiness of air-flow. The production of

[1] "The Technical Report of the Advisory Committee for Aeronautics for the year 1912–13." Pp. 416. (London: Wyman and Sons, Ltd., 1914. Price 10s.

such a channel proved to be very difficult, and the more important of these difficulties are illustrated by records of fluctuations obtained. A satisfactory design was ultimately obtained and put to a full-scale test in the new four-foot channel shown in Fig. 2. The results of this final test were considered to be quite satisfactory, and since that time a three-foot channel has been erected and put into use, whilst a seven-foot channel to the same general design is nearly completed. An almost exact copy of the four-foot channel has been erected at Boston, U.S.A.

From the figure it will be seen that the channel consists of a square trunk, the part from the left to the centre being the working section in which uniform flow is required. The fan is four-bladed and similar to an aeroplane propeller, and is situated in the short circular section to be seen just past the steps. This propeller draws air at speeds up to 50 ft. per sec. through the bell-mouth and a honeycomb, past the model, and through a second honeycomb, finally delivering the air into the perforated chamber or distributor seen to the right of the picture. The air leaves the distributor at speeds less than 3 ft. per sec., and the disturbance of the air cannot easily be detected except within a foot or so of the perforations. The first honeycomb has a use not readily suspected; miniature whirlwinds form on the floor of the building, and unless broken up by a honeycomb, the result on the model is a succession of blows at uncertain intervals. The movement of large bodies of air without the production of vortices is the great problem in the production of a steady wind-channel.

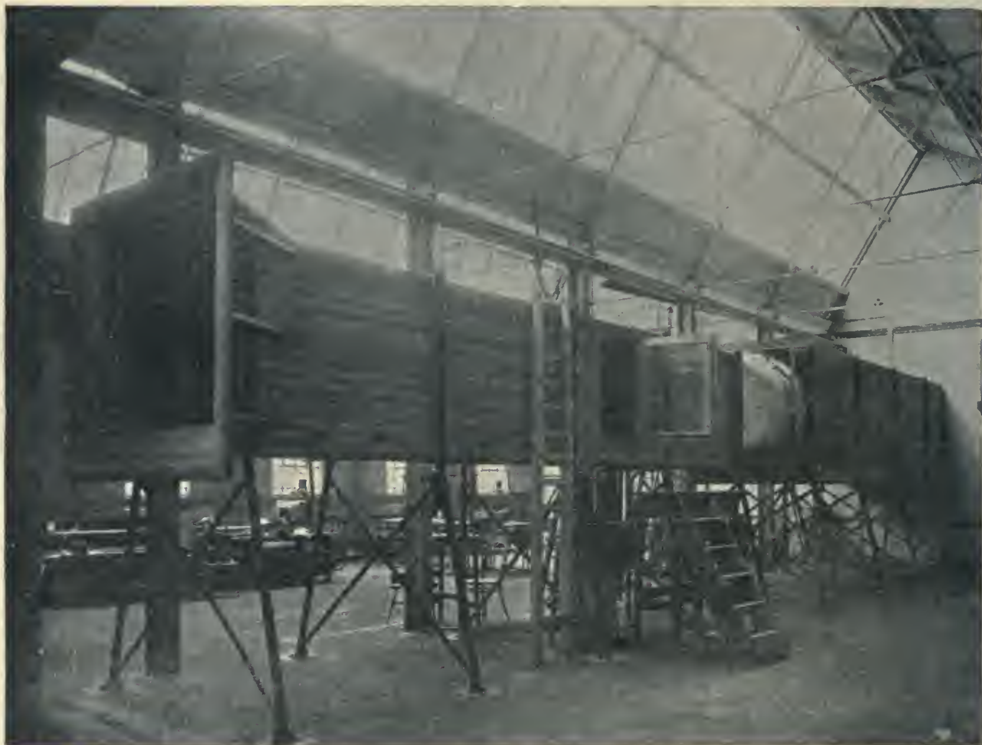

FIG. 2.—General view of the new four-foot wide channel, showing trumpet intake, working section of the channel, and distributor. From "Technical Report of the Advisory Committee for Aeronautics for the year 1912–13." By permission of the Controller of H. M. Stationery Office.

Not only has the air-flow been rendered satisfactory, but the aerodynamic balance has been redesigned and rendered suitable for work of the most general description. It is possible, and has, in fact, become part of the regular work of the National Physical Laboratory, to measure all the forces and couples acting on any body, however unsymmetrically placed on the wind. The precautions taken in the setting of the balance are described in some detail in the report, and show that considerable care is essential to success; the order of accuracy required can be realised from the fact that to obtain the resistance of an aeroplane wing correct to 1 per cent. the wind-direction must be known to within 0·05° relative to the arms of the balance.

There is one measurement other than those provided by the balance which is necessary before the results can be expressed in absolute units, viz. the velocity of the air-current. Experiments have been carried out on the whirling arm of the National Physical Laboratory, from which it has been possible to fix the constant of a standard anemometer to 0·1 per cent., an accuracy which makes the uncertainty in absolute value far less than the errors of observation in most experiments for aeronautical purposes. The accuracy of aeronautical experimental work is often limited by the effects of apparatus for holding the models, and

one of the recurring difficulties is that of reducing such interferences until they are small enough to be dealt with as corrections.

Almost all the numerical data given in the section relating to full-scale machines are derived from the results of experiments on models in a wind-channel. Care is necessary in making the application, and the report contains a comparison between tests on model and full-scale wings. The law of dynamical similarity indicates the possibility of a difference, and although the experimental results are not all that could be desired, they furnish a first approximation to one of a series of scale correction factors.

As a result of model experiments it is now possible to try full-scale experiments of a somewhat detailed character.

Other parts of the report deal with calculations of the stresses in the wings of aeroplanes, both in the internal structure and in the fabric. Systematic investigation of the strength and extensibility of fabric used for aeroplane covering is in progress. The report generally gives detailed descriptions of each of the tests, the results being expressed in many cases in the form of curves.

THE BRITISH ASSOCIATION IN WEST AUSTRALIA.

PERTH, AUGUST 4.

THE Australian meeting of the British Association has already been very successfully inaugurated, to-day being the last spent by the

FIG. 3.—BE2 showing fin experiment F and buffer landing gear B. From "Technical Report of the Advisory Committee for Aeronautics for the Year 1912–13." By permission of the Controller of H.M. Stationery Office.

The test illustrated in Fig. 3 relates to the automatic banking of a flying machine, and the detail changed is the upper end of the wing struts. These had been shown by model experiments to become effective fins and therefore suitable for such an experiment.

For measurements of the resistance of hydroaeroplane floats apparatus must be used in which the surface waves can be reproduced, and work of this character is carried out in the William Froude National Tank. The report gives drawings and the results of experiments for a new type of float having a low resistance.

advance party in Western Australia and the first of the main party travelling by the *Orvieto.*

The Western Australian delegation, numbering close on seventy visitors, has remained a week in the Western State, and this time has been devoted almost entirely to practical work in the country and on the sea. The Western Australian committee from the very first aimed at giving the guests a full week of collecting and investigating, and consequently receptions, garden parties, etc., have been strongly suppressed. That this has been a huge success is evident from the opinions of the visiting men of science, who

consider their week of research in Western Australia has amply repaid them for their long journey from England. No meetings of sections have been held whatever. A number of visitors, chiefly botanists, zoologists, and geologists, arrived early in July in order to spend two, or even three, weeks in the State ending with the official week. The official party arrived by the *Ascanius* on July 28 and the P. and O. mailboat of the same date.

Hospitality had been previously found for all the visitors, and the Government of Western Australia had provided funds for official excursions during the week for the botanists, zoologists, and geologists, together with free railway passes over the State railways.

A very well illustrated handbook had also been printed, and was distributed to the guests on arrival. This handbook is on somewhat different lines from those of the other State handbooks, the articles being chiefly on the sciences represented by the visitors. The various sections include a general introduction by the Hon. W. Kingsmill (chairman of the executive committee in Western Australia); agriculture and climate, by W. Catton Grasby; botany, by C. Andrews and Mrs. C. M. G. Dakin; geology, by A. Gibb Maitland; mineralogy and mining, by A. Montgomery; and zoology, by Prof. W. J. Dakin and W. B. Alexander.

On the day of arrival of the visitors Sir Harry Barron, the Governor of Western Australia, held a reception at which about 2,500 guests were present. The first British Association evening discourse was given the same evening by Prof. Herdman, the title being "Why we Investigate the Ocean," and was very largely attended. Three other lectures have been given in Perth during the week and one in Kalgoorlie. The subjects of the Perth lectures were, "Stars and their Movements," by Prof. Eddington; "The Primitive Methods of Making Fire," by Mr. H. Balfour; and "The Electrical Action of the Heart," by Dr. Waller. The Kalgoorlie lecture by Mr. Buckmaster was on mining education in England.

The excursion parties left Perth on Wednesday morning, the day after arrival, with the exception of a small party of keen geologists which started away under the leadership of Prof. Woolnough, of the University of Western Australia, on the previous day.

Prof. W. J. Dakin, one of the local secretaries for the Western Australia meeting, conducted a large party of zoologists to the famous Yallingup and Margaret River caves, situated near the coast in the south-western corner of the State. This expedition, favoured by remarkably fine weather (exceptional for the season of the year), afforded not only a glimpse of the south-west region, where rain is abundant and the vegetation has many peculiar characters, but enabled the zoologists to visit the deposits where such excellent discoveries of fossil giant marsupials have lately been made by the Western Australian museum staff. These investigations have been carried out through the munificence of Sir Winthrop Hackett by Mr. Glauert. The remains include bones of two species of diprotodon, the Tasmanian wolf (*Thylacinus cynocephalus*), the Tasmanian devil (*Sarcophilus harrisi*), a giant Echidna (*Zaglossus hacketti*), and a giant kangaroo. Space forbids a description of the cave formations—the caves are water-formed chambers in a soft limestone which is due itself to the action of atmospheric agents on great accumulations of drift sand. The second large zoological excursion was a motor run from Perth to Mundaring Weir. A hunt was made for arthropods, the greatest interest centring, of course, round Peripatus. About seventy-five living specimens of the latter (*Peripatoides gilesii*) were collected by the party in a few hours. This excursion was also under the leadership of Prof. Dakin.

The zoologists completed their investigations by a dredging expedition on almost virgin ground, turning up many species new to Western Australia.

The botanists were extremely enthusiastic, and well they might be, for Western Australia is without doubt the pre-eminent State as a "botanist's paradise." To quote the words of Mr. C. Andrews, who was leader of all the botanical excursions, "Nearly four thousand species have already been described, and of the four thousand species about two-thirds are endemic."

The botanists commenced work with an excursion to the Darling Ranges, which occupied a full day. On the following day a longer excursion was made, and the party visited a sand-plain district, making their headquarters at the Benedictine Monastery at New Norcia. The third excursion took the party to the interesting Albany district, where, amongst other plants, the famous Cephalotus (the Western Australian pitcher plant) lives. The most interesting plant collected here was Phylloglossum, but very large collections of the Proteaceæ and other characteristic plants were made.

The geologists had a most strenuous week, especially since some of them had put in a hard week immediately before, for the two official excursions covered a fortnight altogether. The first visitors left Perth for Mingenew (two hundred miles north), and spent three days travelling through the Irwin River Valley and examining the Permo-Carboniferous Glacial beds, Marine beds, and Coal Measures. Two more days were employed in excursions in the vicinity of Perth, and the visitors left for Albany on Monday night (July 27). On the following day the geologists of the main Western Australia party arrived and proceeded to Mount Barker (three hundred miles south), meeting the others at that place. The whole party, under the guidance of Mr. H. P. Woodward, acting Government geologist, motored to the remarkable quartzite mountains of the Stirling Range. The last few days were spent in and about the goldfields.

In completing an account of the week in

Western Australia mention must be made of the excellent arrangements for those visitors who were desirous of seeing as much as possible of the State but were not taking the official botanical, geological, and zoological excursions. Mr. Catton Grasby piloted Mr. Golding round the agricultural districts. Mr. Kingsmill and Mr. Battye arranged a week's programme of short local excursions. The Government very kindly arranged a particularly interesting excursion to the timber district at Big Brook and ran a special train, the Premier himself making one of the party. Prof. Ross guided a number of visitors over the wireless telegraphic station, and Prof. Whitfeld conducted a small party to Kalgoorlie.

Special arrangements were made for the overseas party travelling by the *Orvieto* and only having a few hours in Western Australia. The Mayor of Perth entertained the party to luncheon, after motor drives had been taken round Perth. This completed the official visit to Western Australia. Whilst this is being written upon the *Orvieto en route* for Adelaide the party is anxiously waiting for news of the trouble at home, a few tragic rumours having just reached us as we left Perth for the steamer. W. J. DAKIN.

DR. W. H. GASKELL, F.R.S.

DR. GASKELL'S unexpected death comes as a shock to his many friends. A few weeks ago he was in full enjoyment of life. His sixty-seven years were lightly borne, and the ailments inseparable from his years had little effect on his buoyant nature. He was actively engaged in putting in book form his views on the sympathetic system, and no one doubted that he had years of barely abated vigour before him. He died on September 7 after a short illness.

Gaskell entered Trinity College, Cambridge. In 1869 he was placed among the Wranglers in the Mathematical Tripos, and in 1872 he took honours in the Natural Science Tripos. He proceeded to a medical degree, and under the influence of Michael Foster began research in physiology. Carl Ludwig's laboratory in Leipzig was the principal centre of physiological research, and Gaskell went to Leipzig. Under Ludwig's direction he investigated the vaso-dilator fibres of muscle. The resultant paper is one of the classical works on the subject.

On returning to Cambridge Gaskell took up the study of the mechanism by which the several parts of the heart are coordinated in the sequence of contractions which make up the heart-beat. At this time the dominant—though not unquestioned—theory referred the sequence of contractions to the activity of separate groups of motor and inhibitory nerve-cells placed in the heart itself. Gaskell at first supported this hypothesis with certain modifications, but as the result of later investigations chiefly on the heart of the tortoise, he substituted for it the theory, now almost universally adopted, that the conduction of impulses from one part of the heart to the next is by means of a specialised muscular tissue. At approximately the same time Engelmann contested the theory of nervous control, and the modern views of the mechanism of the heart-beat are inseparably connected with the names of Gaskell and Engelmann. Gaskell's work was full of new and important observations. Thus he described how, by lowering the conductivity of the tissue between the auricle and the ventricle, the ventricle only responded to every second and third contraction of the auricle. On the invention of the string galvanometer by Einthoven, the "heart-block," described by Gaskell, explained certain irregularities observed in the cardiac tracings of man, and became of fundamental clinical importance.

In connection with the foregoing work, Gaskell investigated the extrinsic nervous supply of the heart, *i.e.* its innervation by the vagus and sympathetic nerves. He was thus led to his next great line of work, that on the sympathetic nervous system. On this question there were a vast number of observations, but for the most part they were disconnected, and few generalised statements had any currency. A distinction of white and grey rami connecting in the mammal the spinal nerves with the sympathetic had long been known, and Onodi and others had described the absence of white rami in the cervical, lower lumbar, and sacral regions. The white rami were known to be composed chiefly of myelinated nerves and the grey rami of non-myelinated nerves. Gaskell's observations were chiefly microscopical. He noted that the roots of the spinal nerves at their origin from the spinal cord had no non-myelinated nerve fibres, and from this and other facts he deduced as a broad general statement that the outflow of nerve fibres from the spinal cord to the sympathetic chain took place solely, or almost solely, in the regions in which white rami were present, *i.e.* in the thoracic and upper lumbar regions. In Gaskell's paper there are other generalisations with regard to the sympathetic and allied nervous systems, but it would take too much space to discuss them here. It must suffice to say that Gaskell was the first to attempt to treat the innervation of the blood-vessels and the viscera in a comprehensive manner.

Gaskell's study of the relation of the central nervous system to the sympathetic nervous system in vertebrates led him to consider the relation of both to the nervous system of invertebrates, and he passed from the more special domain of physiology to that of morphology. He arrived at conclusions differing essentially from that held by morphologists, and the remaining years of his life were mainly occupied in advocating his views and working them out in detail.

Taking Gaskell's work as a whole, it appears that the main bent of his mind was for generalisation. It was scarcely possible for him to make an experiment without extending the conclusions to be derived from it to a number of other phenomena. It was both his virtue and his defect. His influence on physiological conceptions has

been widespread, and it will be long before he ceases to be a living force and passes to the position—honourable as it is—of an historical figure in physiological science.

Gaskell cared little for public ceremonies, and rarely attended the congresses which beset the path of prominent scientific men. He loved to work quietly, to cultivate his garden, to see his friends, and to take a hand at whist or bridge. His house at Great Shelford was a recognised meeting-place for physiologists, and his frank and genial welcome will be an abiding recollection to all who knew him. J. N. LANGLEY.

NOTES.

WE learn from a paragraph in the *Times* of September 19 that the question of abandoning honorary degrees received from English universities, and distinctions from learned societies, is being discussed by some German professors. Prof. W. Förster, professor of astronomy in the University of Berlin, who holds a doctor's degree at Oxford, takes objection to the movement in a letter to the *Berliner Tageblatt*, on the ground that it is unwise to proclaim a divorce from the "learned world" of England because of England's "wicked policy." It would be better for the German professors to make a strong appeal to their English friends for "a more effective loyalty to the intellectual community." Protests against Prof. Förster's views promptly came from Profs. Eucken and J. Kohler, who hold chairs of philosophy and law respectively. In connection with this question we are glad to print elsewhere in this issue a letter from Dr. J. P. Lotsy asking scientific men who have received honours from universities, or other learned institutions of nations with which their own countries are at war, not to commit the act of renunciation advocated by certain representatives of German learning.

WE are glad to see in Tuesday's *Times* a letter from Prof. J. A. Fleming dissociating scientific work from the spirit of Prussian militarism. In the course of his letter, Prof. Fleming says:—"No one familiar with the achievements of scientific thought would refuse to admit the indebtedness of the world to such thinkers and workers as Jacobi, Gauss, Bessel, Riemann, H. F. Weber, von Helmholtz, Kirchhoff, Hertz, and Röntgen, but the fact is quite as astonishing as it is painful that a nation which has made such contributions to the upbuilding of natural philosophy should have permitted itself also to be dominated by an immoral militarism by whose votaries sheer brute force is worshipped as the highest virtue and the only source of national advancement. Side by side with immense ability in creating and applying scientific knowledge we have an almost complete failure to recognise truth, honour, faith-keeping, and justice as the foundations of national greatness. Germany has no greater need at the present moment than some inspired prophet to enforce on her the truths of which Thomas Carlyle was so eloquent an exponent—namely, that physical force is in the long run impotent unless backed by those spiritual forces which spring only from loyalty to the everlasting difference between right and wrong."

WE learn with regret that Dr. H. J. Johnston-Lavis, professor of vulcanology in the Royal University of Naples, was killed in a motor accident at Bourges early this month.

WE regret to announce the death of Sir Henry G. Howse, at one time senior surgeon to Guy's Hospital, and president of the Royal College of Surgeons, England. He was eminently a practical surgeon, making numerous contributions to the medical literature of his time. Some years ago he retired from active practice, and settled near Sevenoaks, Kent, where he enjoyed a well-earned leisure. He was in his seventy-third year.

THE death is announced at Louth, Lincs., of Mr. George Gresswell, formerly lecturer in physical science, under the Government of the Cape of Good Hope, at the Diocesan College, Rondebosch, and demonstrator of practical physiology and histology at Westminster Hospital. Mr. Gresswell was the author of a number of books and papers, including several on the theory of evolution.

FROM telegraphic messages issued through Reuter's Agency we learn that the United States Revenue cutter *Bear* on September 8 rescued eight members of Mr. Stefánsson's Canadian Arctic Expedition, who were marooned on Wrangel Island. It is reported that Mr. Mallock, the geologist, and Mr. Mamen, the topographer to the expedition, died on Wrangel Island. The absence of news leads to the fear that M. H. Blanchet, of Paris, Dr. A. Mackay, and Mr. James Murray, other members of the expedition, may have been lost. Mr. Stefánsson himself and three others are said to be safe and to be drifting towards King William Land.

SIR ERNEST SHACKLETON and the members of the Trans-Antarctic Expedition left London on September 18. Those members of the expedition proceeding to the Ross Sea travelled *viâ* Tilbury for Tasmania; the others, the Weddell Sea section, included Sir Ernest Shackleton, and embarked for South America. The Ross Sea party expects to sail from Hobart in the *Aurora*. The Weddell Sea contingent hopes to leave Buenos Aires on October 18 by the *Endurance*. After landing its party the *Endurance* will return to the Falkland Islands, whence news of the explorers may be expected next January. If Sir Ernest Shackleton's land party does not cross the Antarctic Continent during the first season it has been arranged that the *Aurora* shall winter in the Ross Sea. Sir Ernest Shackleton hopes to meet the Ross Sea party either in April of next year, or, failing that, in March, 1916.

UNIVERSITY COLLEGE, Galway, has, during the summer vacation, suffered a great loss by the death of Prof. R. J. Anderson, professor of natural history in the college. Dr. Anderson was greatly beloved by his colleagues and his students. He was a genuine scholar, with few interests outside the world of science. With his wife (a sister of Prof. John Perry, of South Kensington) he was a constant attendant at the meet-

ings of the British Association and the British Medical Association. He graduated in the Queen's University of Ireland, and afterwards studied at London, Leipzig, Paris, Heidelberg, and Naples. For eight years he was lecturer on anatomy and assistant professor of physiology in Queen's College, Belfast, and for more than twenty-five years he occupied the chair of natural history in Galway. He was co-editor of the *International Journal of Anatomy and Physiology*; was an honorary president at Lisbon Medical Congress, Sec. Intermediate I.; an honorary president at Buda Pesth Medical Congress, Sect. Board II.; a vice-president Anatomical Section, British Medical Association, at Glasgow. He made a speciality in his studies of vertebræ skeleton and mammalian morphology. His published works include "The Elephants" (1895), "The Whales and Dolphins" (1896), "Chelonia" (1912), and "German Influence: Intellectual and Moral" (1896). Dr. Anderson graduated M.A. with the highest honours in the Queen's University, and at the examination for the M.D. degree of that University he obtained first place, the Peel scholarship, and a gold medal. He was a member of the Royal College of Surgeons (England).

IN *Man* for August Dr. S. N. Shannus describes a form of iron-smelting furnace used by the Angonis of Nyasaland. The furnace is about 10 ft. in height, bottle-shaped, and made of clay, supported by wooden poles let into the ground, bound round the outside. At the base there are eight holes through which earthenware pipes having an internal diameter of 3 in. are inserted to create the draught. The furnace is built on a slight slope, which allows of a hole being made at the lower side from which the slag escapes. A rough platform of logs is made up against the upper side for the convenience of those filling the furnace. It is filled almost to the neck with charcoal, which is ignited from the top, and a mixture of charcoal and iron-stone in equal proportions is added at intervals. The operation lasts for two days, when an opening is made at the base of the furnace, and the iron, which has collected in a circular trough at the bottom, is extracted.

MR. A. D. PASSMORE discusses in *Man* for August the reason for the absence of large flint implements in Gloucestershire. In this district there is no indigenous flint, and the raw material was probably imported from Wiltshire. In Wiltshire, where flint is common, a man who broke a large axe could afford to throw the pieces away and pick up a fresh lump to replace it. But in Gloucestershire the reverse would be the case, and the pieces would immediately be used up to make arrowheads, scrapers, and the like. At Windmill Hill, near Avebury, Wilts, flakes and pieces of flint which were once obviously parts of axes have been found in great numbers. It has been supposed, in order to explain this fact, that a successful invading race of bronze-using people went round after the conquest smashing up the flint weapons of their victims. This is, he thinks, more probably due to the fact that working material of tried value was used in preference to that which was not tried, and the fragments were the waste remaining after the conversion of broken implements into smaller articles. As a parallel, he quotes the case of a repairer of old furniture using an old table-top which bore a peculiar yellow polish, with the result that small pieces bearing this peculiar polish could be picked up in all corners of the workshop.

IN the report of the Otago University Museum for 1913 it is recorded that considerable additions have been made to the Hocken library, the principal contributors being Mrs. Hocken herself and Mr. Trimble. The curator laments that school teachers neglect the opportunities offered by the museum for instruction in nature-study.

ACCORDING to the report for the year ending June 30, 1914, the most important recent addition to the natural section of the Warrington Museum is the herbarium of the late Mr. W. Hodge, of Northwich, which was acquired by purchase. It includes 931 sheets of flowering plants, representing 824 species, and 121 sheets, with 115 species, of mosses, together with five volumes of notes. Nearly half the specimens were collected locally.

THE biology of humble-bees and honey-bees and the various forms of cells constructed by different kinds of wasps are discussed by Mr. O. J. Lie-Pettersen in the combined July and August number of *Naturen*. Another article on bees appears in the August issue of the Proceedings of the Philadelphia Academy, in which the author, Dr. N. E. McIndoo, describes the scent-producing organ of these insects. This organ, situated between the fifth and sixth abdominal segments, is furnished with gland-cells, which were long considered to be for the purpose of secreting perspiration, but their true function was pointed out by Sladen in 1902. Apparently these glands secrete a volatile substance, which collects in a special reservoir (ampulla), whence it passes through a chitinous tube to a canal on the dorsal surface of the abdomen. So long as the abdomen remains straight, the canal is well protected, and the liquid can only evaporate slowly; but directly this part of the body is strongly flexed, the entire canal is more or less fully exposed to the air, in which the odour of the evaporating fluid becomes rapidly diffused.

A GEOLOGICAL map of Nova Scotia in one sheet, on the scale of one inch to eight miles, has been issued by the Geological Survey of Canada. The Palæozoic sequence is remarkably complete. While the crystalline rocks of Cape Breton Island are clearly pre-Cambrian, a Devonian granite is prominent in the south-west of the country, where it forms the watershed. North-west of it, the coastline of the Bay of Fundy is moulded on the strike of a long band of Triassic dolerite.

DR. F. R. VON HUENE, of Tübingen, summarises the conclusions of his recent work on Dinosaurs in the *American Journal of Science*, vol. xxxviii. (1914), p. 145. He urges that the dinosaurs are not a natural order, and that Seeley's two divisions, the Saurischia (=Theropoda+Sauropoda) and Ornithischia (=Orthopoda), were separately derived from the Pseudosuchia. References are given to his three papers published in Germany in the present year.

THE production of amphibolites, rocks rich in hornblende, felspar, lime-garnet, etc., through the alteration of limestone invaded by a granitic magma, presents features of chemical as well as geological interest. A notable addition to the work done in France, Canada, and elsewhere is made by P. P. Sustschinsky (*Trav. Soc. imp. Naturalistes St. Pétersbourg*, vol. xxxvi., livr. v.), who illustrates a number of examples of contact-alteration from south-west Finland. A German summary is provided.

THE memoir of the Geological Survey of England and Wales on the geology of the northern part of the Derbyshire coalfield (price 3s.), by W. Gibson, C. B. Wedd, G. W. Lamplugh, and others, will be of interest to many besides professed geologists. The area includes Matlock and the famous Creswell Caves, rich in Pleistocene mammalia, and excellent photographs are given of this land of limestone crags. L. Moysey contributes classified lists of Coal-Measure fossils, occupying twenty-two pages, which will be of service to workers throughout central England.

THE stratigraphy of New Zealand has been so retarded, and, it may be added, confused, by the imperfection of the palæontological data, that we welcome the Palæontological Bulletin No. 1, issued by the New Zealand Geological Survey. In this quarto memoir, J. A. Thomson brings together materials for the palæontology of New Zealand, including a list, with references, of all the known pre-Cretaceous fossil species of the country. Plates that have been long in stock are now issued with this publication. We note what is perhaps an appeal to a new group of helpers in national scientific work in the addition of Maori names for the islands, and for New Zealand itself, in the two topographical maps that are so well provided.

So much interest has been attracted to the antarctic regions that it may be well to mention a paper published in the *Cairo Scientific Journal*, vol. viii. (1914), p. 77, by H. T. Ferrar, who accompanied the *Discovery* in 1901. The summary of geological conclusions indicates the occurrence of both "Atlantic" and "Pacific" types of crust-structure in the antarctic continent. The author urges that the shrinkage of the glaciers is due to decreased precipitation on the higher ground, and that the cause of this is "a general lowering of the temperature of the polar atmosphere." It must be remembered, on the other hand, that ice-sheets may be nourished by small annual precipitation, provided that the conditions are cold enough to reduce the loss by evaporation and ablation. Geographers may overlook this paper in an Egyptian journal, and may also be glad of a reference to a description by W. Bellows, accompanied by a good panoramic photograph, of the rarely seen arctic island of Jan Mayen. This appeared in the Proceedings of the Cotteswold Naturalists' Field Club, vol. xvii., p. 333.

WITHIN less than a year seismology has lost two of its leading students. Prof. Milne died on July 31, 1913, and Prof. G. Mercalli, through fire in his house at Naples, on March 19, 1914. Born on May 21, 1850, and therefore only a few months older than Milne, Mercalli's attention was concentrated at an early age on the study of volcanoes and earthquakes. His first important work was that on the "Vulcani e fenomeni vulcanici in Italia" (1883), which formed the third part of the "Geologia d'Italia" by G. Negri, A. Stoppani, and G. Mercalli. In partnership with Prof. T. Taramelli, who contributed the geological parts of the reports, he studied the Andalusian earthquake of 1884 and the Riviera (Ligurian) earthquake of 1887. In 1902, he proposed the modification of the Rossi-Forel scale of seismic intensity which now bears his name, and is widely, almost universally, used throughout Italy. As a seismologist, Mercalli will perhaps be remembered chiefly for his contributions to the physiographic side of his science. He prepared a general catalogue of Italian earthquakes from 225 B.C. to A.D. 1859, and the generosity of his disposition is shown by the help which he gave to Dr. Baratta in the work by which this catalogue has now been superseded. One of his earliest detailed studies of earthquakes was that on the destructive Ischian earthquake of 1883; and he has since (1897) published important memoirs on the earthquakes of Liguria and Calabria. Few, if any, of the Italian volcanoes have escaped the attention of Mercalli, but to the Vesuvian phenomena he devoted unremitting study for a period of about twenty years. An admirable summary of his scientific work by Dr. E. Oddone appears in the last *Bollettino* of the Italian Seismological Society (vol. xvii., pp. 245–262).

IN view of the unfortunate interruption to the useful work of the international exploration of the upper air, owing to the war now raging over Europe, it is satisfactory to note that there are several stations in the British Isles at which such observations are regularly made. The annual supplement of the *Geophysical Journal*, 1912, recently published by the Meteorological Office, contains a summary of the records of registering balloon ascents at six stations, and additional data not included in the monthly issues. The results of fifty-two successful ascents were published during the year in question, and it is stated that there was scarcely a single failure in obtaining a trustworthy record up to at least 10 km., but that the year was an unfortunate one in the matter of finding the balloons. The more salient features of each ascent are brought together in one table and expressed in international units, from which, among other interesting results, it is seen that the mean height of the base of the stratosphere was 10 km., and the corresponding temperature 218·5° A. (273° A.=0° C.); temperature at the mean maximum height reached (14·7 km.) 221°; mean temperature of the air column between 1 and 9 km., 251·8° It should be noted that most of the ascents were made in the summer season. Out of the falling points of the balloons there were twenty-two in the S.E. and fourteen in the S.W. quadrant; the preponderance of falls in the former quadrant agrees with continental observations.

IN the Memoirs of the Indian Meteorological Department (vol. xxi., part ix.), Dr. G. T. Walker publishes a short note on the criterion for the reality of

relationships or periodicities. If an attempt is made to correlate a pair of variable quantities there is a certain measure of correlation to be expected even in the absence of any definite relationship. This measure must be sensibly exceeded if the result actually found is to be treated as an indication of causal connection. When, however, a whole set of correlations is determined the fortuitous element will occasionally be largely exceeded without indicating a real relation. Similarly, when a complete periodogram is investigated the largest ordinate must exceed the probable measure by a large factor if the corresponding periodicity is to be regarded with any confidence. The outcome of Dr. Walker's paper is a table giving the ratios of the greatest of an assigned number of (1) accidental correlation coefficients, (2) amplitudes of periodicities, to the probable value of a single one. The note illustrates the need for extreme caution in interpreting the results of work of this kind. But it does not touch the real difficulty of periodogram analysis. This consists, in the language of the optical analogy, in the occurrence of banded spectra. Until this feature becomes amenable to sound interpretation, the periodogram method, always painfully laborious, is likely to remain absolutely sterile.

From the recently issued report of the Government Chemist (Cd. 7562) we learn that a large number of determinations of the salinity of sea-water were made last year at the Government Laboratory, for the information of the Permanent International Council dealing with the exploration of the sea. More than four thousand samples of sea-water were taken by steamships on various routes and by lightships round the coast, and forwarded for examination. The data relating to the specimens from the Atlantic routes are published with the monthly charts issued by the Meteorological Office. It is noted in the report that the chemical work of the Geological Survey is in future to be performed by the staff of the Government Laboratory, and arrangements have been made for this purpose. During the year an extensive series of experiments was conducted in connection with the measures to be taken for the preservation of the roof of Westminster Hall; the results are not stated, but a summary of the conclusions arrived at has been published as an appendix to the report of the architect in charge of the work. There is an interesting reference by the Government Chemist to the composition of a series of medieval wax seals, of various dates from the thirteenth to the sixteenth centuries, which were examined for the Record Office. An impression of the Great Seal of 1350 was found to consist of pure beeswax which, although nearly six centuries old, corresponded exactly in properties with wax of recent origin. Among other matters of interest mentioned are some experiments upon the keeping of milk in galvanised-iron vessels: the results showed that at the end of twenty-four hours the milk had dissolved zinc equal to about half a grain per pint, and also traces of antimony and arsenic. There was a large increase in the total number of samples examined last year as compared with the previous year, the respective numbers being 234,754 and 209,502.

Part v. of vol. xxvi. of the Proceedings of the Physical Society of London consists of 114 pages of papers communicated to the society, the index to the volume and the proceedings at meetings of the society during the session 1913–14. Readers of the Proceedings will, we feel sure, cordially welcome the issue of them with their edges cut. It will be noticed that the society has a committee on nomenclature and symbols which makes a provisional report on electric and magnetic symbols in the present number. Communications dealing with electrical subjects show a marked preponderance over those relating to other branches of physics. Of the electrical papers may be mentioned Mr. F. E. Smith's on a variation magnetograph, Mr. F. Mercer's on the arc electric wave generator, Prof. Fleming's on the bending of such waves round the earth, and Sir Joseph Thomson's account of his search for waves still shorter than those hitherto produced. A paper by Mr. T. Barrett deals with the thermal and electric conductivities of rare metals, and one by Prof. Lees with Fourier series and the method of least squares.

Prof. F. C. Lea, of the University of Birmingham, and Mr. O. H. Crowther give an account in *Engineering* for September 18 of some experiments on reinforced concrete beams. In these experiments the longitudinal strains of a part of the beam subjected to uniform bending moment were measured by a special type of extensometer. From the resulting curves, it appears that the ordinary assumption that the distribution of stress is linear on the compression side of the neutral axis is approximately correct. The experiments show also that the modular ratio diminishes as the stress increases, and is slightly higher for the richest mixture than for the poorer mixtures. The evidence so far is opposed to the recent London County Council Regulations, but the authors consider that it is desirable that the experiments should be continued, and have made arrangements for this to be done.

OUR ASTRONOMICAL COLUMN.

A New Comet.—It is announced that a bright comet was discovered at the Cape Observatory on September 18. The comet was then near the star Achernar (α Eridani), and therefore invisible in the British Isles.

Comet 1913*f* (Delavan).—Comet Delavan is now beginning to diminish more rapidly its northern declination, but is still a circumpolar object, and therefore visible throughout the whole night. It is a conspicuous object to the naked eye, and lies nearly on the prolongation of a line towards the horizon joining the two pointers (α and β) in Ursa Major. This position can be easily found by consulting the chart given in this column for September 3. The comet is steadily increasing in brightness, and its tail has considerably increased in length. The dark nights recently experienced have been very favourable, both for visual and photographic work, and no doubt a large harvest of data is being collected.

M. Bigourdan, in the *Comptes rendus* for September 7 (tome clix., No. 10), gives some observations for position of this comet which he made at the Paris Observatory on September 2 and 3.

HYDROGEN LINES AND SERIES CONSTANT.—Under the heading "Wave-lengths of Hydrogen Lines and Determination of the Series Constant," Mr. W. E. Curtis recently communicated through Prof. Fowler an important paper to the Royal Society (Roy. Soc. Proc., Series A, vol. xc., No. A 622). The object of the research was first to obtain with the utmost accuracy the wave-lengths of the lines in the Balmer or series spectrum of hydrogen in order to test the formula and make such modifications of it as were considered necessary. Another part of the research restricted itself to the evaluation of the international system of wave-lengths of the constant occurring in the formula; the importance of this constant will be appreciated when it is stated that it may be used in all formulæ representing series of lines. The degree of accuracy which could be obtained with the spectrograph employed (10 ft. concave grating) using the new international standards of wave-length was next investigated. The results of the research are summed up as follows. The wave-lengths in I.A. of the first six lines of the hydrogen series were determined with an accuracy of about 0·001 Å.U. Balmer's formula was found to be inexact and the results could be represented by a modified Rydberg formula containing only two constants. An accuracy of 0·001 Å.U. was attainable in the third order of the grating spectrograph with exposures of less than half an hour. With longer exposures the determination became less accurate owing to the uncontrolled temperature of the instrument. The tertiary iron arc standards determined by Burns were tested in the special regions under investigation and found very satisfactory.

A NOVEL FORM OF ROWLAND GRATING MOUNTING.—Dr. A. S. King, in the Contributions from the Mount Wilson Observatory, No. 84 (*Astrophysical Journal*, vol. xl., 1914), describes a vertical adaptation of the Rowland mounting for a 15-ft. concave grating which has recently been mounted in the Pasadena laboratory of the Mount Wilson Solar Observatory. The general arrangement is as follows:—The plate-holder moves on a horizontal track, at a convenient distance above the floor, supported by a frame of channel iron placed over a slot in the cover of the pit used for the already existing vertical Littrow spectrograph. The slit is at one end of the horizontal track and vertically above the grating, and is contained in a hollow iron casting with a brass collar, which holds the slit tube and permits the adjustment of the height of the slit. The grating is contained in a cast-iron box with an extension which is bolted to the web of a girder connecting with the plate-holder carriage. The grating box is fixed to a carriage which is capable of movement on a vertical track, and an ingenious arrangement is adopted to allow for the variable pull when the grating is being raised by the movement of the plate-holder carriage along the horizontal track. Dr. King describes many interesting details about this variable counterweight system, the plate-holder carriage, photographic plate-holder, etc. While the mounting retains all the good features of the usual Rowland form, there are many distinct advantages. In the first place, there is an excellent temperature control in the pit, the grating and connecting girder benefiting thereby. The mounting requires little floor space, a narrow space against a wall being all that is necessary. No darkening of the room is necessary, and therefore no interference with other work being carried on in the laboratory. For assistance in planning the instrument Dr. King refers to Mr. Pease for designing the main structural features, to Mr. Nichols for numerous devices in convenience of working, and to Mr. Ayers and Mr. Shumway for construction and mounting.

THREE NEW INDIAN METEORITES.—At a meeting of the Asiatic Society of Bengal held on August 5 Mr. Coggin Brown read an interesting account of the fall of meteorites in India which had been described by Mr. C. A. Innes, the acting collector of Malabar. It seems that meteoric stones fell on April 6 last at Kuttayi, Triprangode, Trikanapuram, and Kuttippuram, places in the Pounani taluk of the Malabar district. These places are practically in a straight line, Kuttayi being on the coast and Kuttippuram nine or ten miles easterly from the last-mentioned place. Triprangode is about three miles from Kuttayi, Trikanapuram about five miles from Triprangode, and Kuttippuram about two miles from Trikanapuram. Four small stones are reported from Kuttayi, one from Triprangode, and six from Trikanapuram. One large stone, weighing 71 lb., fell at Kuttippuram, but it is now in three pieces. The account then describes the appearances of the fall at the different stations. As regards the large stone which fell at Kuttippuram, it is stated "the stone fell in a paddy field which was then dry and penetrated some feet into the ground. A cloud of dust rose into the air, and this cloud attracted people to the spot. But they were apparently afraid to touch the stone, and it was not until some hours later that it was dug out, and then it was quite cold. The people who gathered at the spot say that for some minutes after the fall there was a smell of backwater mud in the vicinity. Backwater mud or silt is black, oozy stuff, which is full of rotting organic matter, and its smell, which is familiar to everyone who lives in Malabar, is most unpleasant." The noise of the first two loud reports is said to have been heard at various places in Malabar. It was heard distinctly at Pounani, 4·5 miles from Kuttayi, and was recorded as having been heard at Calicut, a distance of thirty miles north of Kuttayi.

THE LANCASHIRE SEA FISHERIES LABORATORY.[1]

WE have recently received the report for 1913 on the Lancashire Sea Fisheries Laboratory at the University of Liverpool and the Sea Fish Hatchery at Piel, edited by the honorary director of the scientific work, Prof. W. A. Herdman, F.R.S.

It appears that more than one million plaice and twelve million flounders were hatched at Piel and committed to the sea. The usual course of instruction for fishermen was given, and nature-study evening classes were restarted on behalf of the Education Committee of Barrow, both with satisfactory results. In connection with the classes for fishermen, a new edition of the syllabus has been published and brought up to date by Dr. Johnstone, while a section on navigation by Captain Thornber has been included. There is also appended an excellent series of biological photographs by Mr. A. Scott.

Various observations arising out of mackerel investigations by Mr. Scott are given, particularly with regard to the food of the mackerel, and also a report on the distribution and periods of occurrence of pelagic fish eggs. The seventh annual survey of the work on the intensive study of Irish Sea plankton is submitted by the director, together with some observations on the summer plankton of the west coast of Scotland. The records of the work done by Dr. Johnstone in connection with diseases of fishes are incorporated, as is also a continuation of his detailed work on the measurements of plaice, the latter being of particular interest in view of the proposal by the International Fisheries Bureau to impose limits on

[1] Report on the Lancashire Sea Fisheries Laboratory for 1913. No. xxii.

the size of plaice to be landed. The results of Dr. Johnstone's plaice-marking experiments are also given.

Mr. William Riddell continues his hydrographical investigations, and the results of the chemical analyses of the water samples and a dissertation on their import are given by Prof. Bassett. As part of a proposed general scheme of investigation of the British herring races arranged by the Board of Fisheries, several samples of herrings from the Welsh coast and from the Smalls were examined and the measurements are detailed in the report. A paper of a preliminary nature on sea-bottom deposits and fish food off the Lancashire and Cumberland coasts is contributed by Mr. R. Ray. Dr. Johnstone gives a topographical description of the mussel grounds in the Ribble Estuary and several other Welsh beds. From the results of a bacteriologial analysis, also given, much sewage contamination seems to exist at several of the grounds.

Two important papers by Prof. Moore and his collaborators are given on the debated question of the ability of marine animals to subsist on the organic carbon dissolved and in suspension in sea-water. The results seem to prove conclusively that such subsistence for long periods is impossible, and that neither dissolved organic matter nor the average amount of suspended plankton suffices to account for the nutrition of the larger marine organisms.

Several minor reports conclude the survey of the year's work.

THE METROPOLITAN WATER SUPPLY.[1]

THE two reports by Dr. A. C. Houston, director of water examination, recently issued by the Metropolitan Water Board, show how much is now being done to safeguard from contamination with dangerous micro-organisms the metropolitan water supply, which is admittedly largely derived from sewage-polluted sources. The eighth annual report gives the results of the chemical and bacteriological examination of the London waters for the twelve months ended March 31, 1914. In the introduction Dr. Houston points out that experience in the Water Board laboratories indicates that *Bacillus coli* is practically totally absent from pure waters; in ten specially devised experiments with the Twins well (Deptford) water, typical *B. coli* was absent from 10,000 c.c., and it has been abundantly shown that it is possible, at a not impracticable cost, so to purify the raw river waters that the final product contains no typical *B. coli* in 100 c.c. in more than 80 per cent. of the samples.

In the tenth report on research work, the results of several important researches are detailed. The search for the typhoid bacillus and similar micro-organisms in raw river water and crude sewage has been continued, but although a large number of samples has been examined, none has been found. Various methods for the isolation of the typhoid bacillus in these circumstances are reviewed.

A study of the streptococci present in excremental matters has not resulted in finding any definite difference between those present in human, and those present in animal, excrement.

The value of storage as a means of eliminating pathogenic micro-organisms and of lime as a bactericidal agent are further confirmed in series of new experiments.

[1] Metropolitan Water Board (*a*) "Eighth Annual Report" on the results of the Chemical and Bacteriological Examination of the London Waters for the twelve months ended March 31, 1914. (*b*) "Tenth Report on Research Work." Both by Dr. A. C. Houston, Director of Water Examination, Metropolitan Water Board.

Altogether these two reports are worthy of careful perusal by public health authorities and bacteriologists, and show how much valuable but unobtrusive work is being done by Dr Houston and his staff.

R. T. HEWLETT.

LOCAL CASE-HARDENING OF STEEL.[1]

IN a paper read to the Société d'Encouragement pour l'Industrie National, MM. Guillet and Bernard discuss the various methods employed when it is desired to case-harden steel objects in certain parts only. The methods used are:—

(1) The parts to be protected against cementation are covered with fire-clay. The protection thus furnished is not complete, as the gases penetrate the fire-clay. Also in complex shapes the method becomes complicated and expensive.

(2) A tube is shrunk over the parts to remain uncemented, the thickness of the tube being slightly greater than the depth of case required. After the end of the cementing process, the tube is broken off. This method is obviously very limited in its application.

(3) The object is made with extra thicknesses in those parts which must not be hardened. After cementation and before hardening, these extra thicknesses are machined off. This process is very expensive.

(4) The parts not to be cemented are protected by a metallic deposit which must be (*a*) solid at the cementing temperature, (*b*) impervious to the cementing materials, (*c*) easily obtained commercially, and (*d*) easily removed after the operation. Copper and nickel are the only metals which fulfil conditions (*a*) and (*c*), and the latter fails to comply with condition (*b*).

The metal may be deposited by immersion in a salt solution, by electrolysis, or by the Schoop spraying process. The first mentioned is not satisfactory owing to the thinness and uncertain adherence of the coating. The electrolytic process is cheaper to instal than the spray process, which, on the other hand, is quicker and more easily localised.

The authors also consider the question of diffusion of metals. They show that for this to take place, (1) the two metals must be capable of forming solid solutions with each other, (2) they must be in very good contact, and (3) the temperature must be between the limits at which the solid solution exists. The higher the temperature, the greater is the rate of diffusion. They conclude that the diffusion of solids into solids is a very common phenomenon, which in certain cases (*e.g.* tinned condenser tubes) may introduce very considerable changes into the properties of the metal.

[1] Les réserves en cémentation et la diffusion dans les solides." By MM. Léon Guillet and Victor Bernard. *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, vol. cxxi, No. 5. Pp. 588–618.

THE AUSTRALIAN MEETING OF THE BRITISH ASSOCIATION.

SECTION K.

BOTANY.

OPENING ADDRESS BY PROF. F. O. BOWER, D.Sc., F.R.S., PRESIDENT OF THE SECTION.

To preside over the botanical section on the occasion of its first meeting in Australia is no slight honour, though it also imposes no small responsibility. We members from Great Britain have a deep sense of the advantage which we derive from visiting these distant shores. I am doubtful whether any scientific

profit we can confer by our coming here can balance that which we receive; while over and above this is the personal kindliness of the Australian welcome, which on behalf of the visitors of this section from the Old Country I take this opportunity of gratefully acknowledging. Of the members of the British Association, those who pursue the natural sciences may expect to gain most by their experiences here; and perhaps it is the botanists who stand to come off best of all. Living as most of us do in a country of old cultivation, the vegetation of which has been controlled, transformed, and from the natural floristic point of view almost ruined by the hand of man, it is with delight and expectation that we visit a land not yet spoilt. To those who study Ecology, that branch of the science which regards vegetation collectively as the natural resultant of its external circumstances, the antithesis will come home with special strength, and the opportunity now before them of seeing Nature in her pristine state will not, I am sure, be thrown away.

I may be allowed here to express to the Australian members of the section my regret that the presidency for this occasion should not have fallen to one who could with unusual weight and knowledge have addressed them from the floristic and geographical point of view. I mean, to Professor Bayley Balfour, of Edinburgh, who was actually invited by the Council to preside. He could have handled the subject of your rich and peculiar flora with detailed knowledge; and, with the true Hookerian touch, he would have pictured to you in bold outlines its relation to present problems. Failing such equipment, I may at least claim to have made some of your rare and peculiar forms the subject of special study at intervals spread over thirty years: for it was in 1884 that I was supplied with living plants of Phylloglossum by Baron Ferdinand von Müller, while a paper to be published this year contains details of a number of ferns kindly sent to me by various collectors from New Zealand. I have been personally interested more especially in your rare Pteridophytes, isolated survivals as they surely are of very ancient vegetation. I propose to indicate later in this address some points of interest which they present. But first I shall offer some more general remarks on the history of the investigation of the Australian flora, as a reminder of the recent death of Sir Joseph Hooker, whose work helped so greatly to promote a philosophical knowledge of the flora of this quarter of the globe.

Few, if any, of the large areas of the earth's surface have developed their coat of vegetation under such interesting conditions as that which bears the Australasian flora. In its comparative isolation, and in its freedom from the disturbing influence of man, it may be held as unique. We may picture to ourselves the field as having been open to evolutionary tendencies, unusually free from the incursion of competitive foreign types, and with its flora shaped and determined through long ages in the main by climatic influences. Naturally the controlling effect of animal life had been present throughout, as well as that of parasitic and fungal attack; but that potent artificial influence, the hand of man, was less effective here than in almost any other area. The aborigines were not tillers of the soil: in their digging for roots and such-like actions they might rank with the herbivorous animals, so far as they affected the vegetation. Probably the most powerful influence they exercised was through fire. And so the conditions remained, the native flora being practically untouched, until the visit of Captain Cook in 1770: for little account need be taken of the handful of specimens collected by Dampier in the seventeenth century.

Captain Cook shipped with him in the *Endeavour* a very remarkable man, viz., Joseph Banks, whom Dr. Maiden has described as "the Father of Australia." He not only acted as the scientific director of the expedition, but he was also its financier. Educated at Eton and Oxford, he found himself as a young man possessed of an ample fortune. Though devoted to field sports, he did not, like so many others, spend his life upon them. Following the dictates of a taste early awakened in him, he turned his attention to travel for scientific ends. His opportunity came when Cook was fitting out the *Endeavour* for his first voyage to the Southern Seas. Banks asked leave of the Admiralty to join the expedition, which was granted, and he furnished all the scientific stores and a staff of nine persons at his own expense.

The story of that great expedition of 1768 to 1771 is given in "Cook's Voyages," compiled by Dr. Hawkesworth, a book that may be found in every library. Though it is evident throughout that Banks took a leading part in the observational work of the expedition, it has not been generally known how deeply indebted Hawkesworth was to Banks for the scientific content of his story. This became apparent only on the publication of Banks's own Journal 125 years after the completion of the voyage. The circumstances of this have a local interest, so I may be excused for briefly relating them.

Banks's papers, including the MS. Journal, passed with his library and Herbarium on his death to his librarian, Robert Brown. On the death of the latter they remained in the British Museum. But after lying there for a long period they were claimed and removed by a member of Banks's family, and were put up for auction. The Journal was sold for *7l. 2s. 6d.*, and the last that has been heard of it is that it came into the possession of a gentleman in Sydney. Perhaps it may be lying within a short distance of the spot where we are now met. This valuable record, fit to rank with Darwin's "Voyage of the *Beagle*," or Moseley's account of the "Voyage of the *Challenger*," might thus have been wholly lost to the public had it not been for the care of Dawson-Turner, who had the original transcribed by his daughters, helped by his grandson, Joseph Dalton Hooker. The boy was fascinated by it, and doubtless it helped to stimulate to like enterprises that botanist to whom Australia owes so much. The copy thus made remained in the British Museum. Finally, from it in 1896 Sir Joseph Hooker himself edited the Journal, in a slightly abridged form. It is now apparent how very large a share Banks actually took in the observation and recording, and how deeply indebted to him was the compiler of the account of the voyage published more than a century earlier, not only for facts, but even for lengthy excerpts.

The plants collected in Australia by this expedition amounted to some 1000 species, and with Banks's Herbarium they found, after his death, a home in the British Museum. Several minor collections were subsequently made in Australia, but the next expedition of prime importance was that of Flinders in 1801 to 1805. What made it botanically notable was the presence of Robert Brown. Hooker speaks of this voyage as being, "as far as botany is concerned, the most important in its results ever taken." The collections came from areas so widely apart as King George's Sound, Southern Tasmania, and the Gulf of Carpentaria. These together with Banks's plants and other minor collections, formed the foundation for Brown's "Prodromus Floræ Novæ Hollandiæ," a work which was described in 1860 by Sir Joseph Hooker as being "though a fragment . . . the greatest botanical work that has ever appeared." It

was published in 1810. I must pass over without detailed remark the notable pioneer work of Allan Cunningham, and of some others. The next outstanding fact in the history of Australian botany was the voyage of Ross, with the *Erebus* and the *Terror*; for with him was Joseph Hooker, whose botanical work gave an added distinction to an otherwise remarkable expedition.

The prime object of the voyage was a magnetic survey, and this determined its course. But in the intervals of sailing the Antarctic Seas the two ships visited Ascension Island, St. Helena, the Cape, New Zealand, Australia, Tasmania, Kerguelen Island, Tierra del Fuego, and the Falkland Islands. Thus Hooker had the opportunity of collecting and observing upon all the great circumpolar areas of the Southern Hemisphere. He welded together the results results into his great work "The Antarctic Flora." It was published in six large quarto volumes. In them about 3000 species are described, while on 530 plates 1095 species are depicted, usually with detailed analytical drawings. But these magnificent volumes did not merely contain reports of explorations, or descriptions of the many new species collected. There was much more than this in them. All the known facts that could be gathered were incorporated, so that they became systematically elaborated and complete floras of the several countries. Moreover, in the last of them, the "Flora Tasmaniæ," there is an introductory essay, in which the Australasian flora was for the first time treated as a whole, and its probable origin and its relation to other floras discussed. Further, questions of the mutability and origin of species were also raised in it. The air was full of such questions in 1859; the essay was completed in November of that year, less than twelve months after the joint communications of Darwin and Wallace had been made to the Linnean Society, and before the "Origin of Species" was published. It was to this essay that Darwin referred when he wrote that "Hooker has come round, and will publish his belief soon." But this publication of his belief in the mutability of species was not merely an echo of assent to Darwin's own opinion. It was a reasoned statement advanced upon the basis of his own "self-thought," and his own wide systematic and geographical experience From these sources he drew support for "the hypothesis that species are derivative and mutable." He points out how the natural history of Australia seemed specially suited to test such a theory, on account of the comparative uniformity of the physical features being accompanied by a great variety in its flora, and the peculiarity of both its fauna and flora, as compared with other countries. After the test had been made on the basis of the study of some 8000 species of plants, their characters, their spread, and their relations to those of other lands, Hooker concluded decisively in favour of mutability, and a doctrine of progression. After reading this essay, Darwin wrote that it was to his judgment "by far the grandest and most interesting essay on subjects of the nature discussed I have ever read."

But beyond its historical interest in relation to the "Origin of Species," Hooker's essay contained what was up to its time the most scientific treatment of a large area from the point of view of the plant-geographer. He found that the Antarctic, like the Arctic flora, is very uniform round the globe. The same species in many cases occur on every island, though thousands of miles of ocean may intervene. Many of these species reappear in the mountains of Southern Chili, Australia, Tasmania, and New Zealand. The southern temperate floras, on the other hand, of South America, South Africa, Australia, and New Zealand differ more among themselves than do the floras of Europe, Northern Asia, and North America. To explain these facts Hooker suggested the probable former existence, during a warmer period than the present, of a centre of creation of new species in the Southern Ocean, in the form of either a continent or archipelago, from which the Antarctic flora radiated. From the zoological side a similar difficulty arises, and the hypothesis of a land-connection has been widely upheld, and that it existed as late as Mid-Tertiary times. The theory took a more definite form in the hands of Osborn (1900), who pictured relatively narrow strips of land connecting respectively South America on one side and Tasmania and New Zealand on the other with the existing Antarctic land area. This would accord well enough with the suggestion of Lothian Green, that the plan of land-elevations on the earth is approximately tetrahedral; and it is, I believe, in line with the views of those who are best informed on Antarctic geography and geology, as studied from the land itself. It may be hoped that further Antarctic discovery may bring fresh facts to bear upon this question, for it is to the positive data acquired from study of the earth's crust that we must look, rather than to the exigencies of botanists and zoologists, for its final solution.

But the hypothesis of an Antarctic land-connection has been held open to doubt in various quarters. As Sir Wm. Thistleton-Dyer has recently pointed out, Darwin himself dissented, though regretfully, from the sinking of imaginary continents in a quite reckless manner, and from the construction of land-bridges in every convenient direction. From the geological side Dana laid down the positive proposition that the continents and oceans had their general outline and form defined in earliest time. Sir John Murray, whose recent death we so deeply deplore, was an undeniable authority as to the ocean-floor. He wrote quite recently with regard to Gondwana-land, that "the study of ocean-depths and ocean-deposits does not seem in any way to support the view that continental land has disappeared beneath the floor of the ocean in the manner indicated." He suggested that the present distribution of organisms is better interpreted by the North Polar theory of origin. The "continuous current of vegetation" southward at the present time was recognised by Hooker himself, and definite streams of northern forms have been traced by him extending even to Australia and Tasmania. This might account for much in present-day distribution; though it seems doubtful whether it would fully explain the extraordinary distribution of Antarctic plants. The problem must for the present remain open.

This whole question, however, has a connection with the still wider difficulty of the existence within the Polar area of ancient floras. In the north the fossils are even of subtropical character. Coal has been found in lands with a five months' night. How did such plants fare if the seasonal conditions were at all like the present? To explain this it would be a physiological necessity to assume either an entirely different climatal condition in those regions from that of the present time; or, as has been suggested, some shifting or creeping of the earth's crust itself. These are, however, questions which we cannot undertake to discuss with effect in the Botanical Section. We must not do more than recognise that an unsolved difficulty exists.

We pass now from Hooker's great work to the last of the classical series, viz. the "Flora Australiensis" of Bentham and Baron Ferdinand von Müller. It is

embodied in seven volumes, and was completed in 1878. Bentham, while assenting in his "concluding preface" to the principles laid down by Hooker in the Tasmanian flora, recognised as the chief component part of the present flora of Australia the indigenous genera and species, originated or differentiated in Australia, which never spread far out of it. Secondly, an Indo-Australian flora showing an ancient connection between Australia and the lands lying to the north. It is represented especially in tropical and subtropical East Queensland. Then there is the mountain flora common to New Zealand, and extending generally to the southern extra-tropical and mountain regions, while other constituents are ubiquitous maritime plants, and those which have been introduced since the European colonisation. But the most remarkable, as they are the least easily explained, are some few plants identical with species from North and West America, and from the Mediterranean. They are stated to be chiefly annuals, or herbaceous or shrubby plants; free-seeders; while their seeds long retain the power of germination. This may perhaps give the clue to this curious conundrum of distribution.

It has been fortunate that the duty of working out this remarkable flora should have fallen into the hands of such masters as Robert Brown, Sir Joseph Hooker, and Bentham. The foundations were thus surely laid. The further progress of knowledge has been carried on by the late Baron Ferdinand von Müller, and it may be confidently left in the hands of others who are still with us. The completion of the task of observing and recording may still be far ahead. But I may be pardoned if I utter a word of anticipatory warning. There is at the present time a risk that the mere work of tabulating and defining the species in a given country may be regarded as the only duty of a Government botanist; that, whenever this is completed, his occupation will be gone. Some such erroneous idea, together with a short-sighted economy, is the probable explanation of the fact that certain positions hitherto held by professional botanists have recently been converted into positions to be held by agriculturists. In the countries where this has happened (and I refer to no part of Australasia) the vegetation had been very adequately, though not yet exhaustively, worked, as regards the flowering plants and ferns. But who that knows anything about plants would imagine that the ascription to a genus or order, or the designation by a couple of Latin names with a brief specific description, exhausts what it is important to know about a species? In most cases it is after this has been done that the real importance of its study begins. Such possibilities as these do not appear to have been appreciated by those who advised or controlled these official changes. I have no desire to undervalue the agriculturist or the important work which he does. But he is engaged in the special application of various pure sciences, rather than in pure science itself. Advance in the prosperity of any country which has progressed beyond the initial stages of settlement follows on the advance of such knowledge as the devotee of pure science not only creates, but is also able to inculcate in his pupils. It is then imperative that, in any State which actively progresses, provision shall be made for the pursuit of pure as well as of applied science. In my view an essential mistake has been made in changing the character of the appointments in question from that of botanists to that of agriculturists. For the change marks the abandonment of pure science in favour of its specialised and local application.

The head of such an institution should always be a representative of pure science, thoroughly versed in the nascent developments of his subject. He could then delegate to specialists the work of following out in detail such various lines of special application as agriculture, acclimatisation, plant-breeding, forestry, or economics. Or, if the organisation were a large one, as we may anticipate that it would become in the capital of a great State, separate institutes might develop to serve the several applied branches, while to a central institute, in touch with them all, might be reserved the duty of advancing the pure science from which all should draw assistance and inspiration.

It matters little how this principle works out in detail, if only the principle itself be accepted, viz., that pure science is the fount from which the practical applications spring. Sydney, as the capital of a great State, has already laid her course, as regards botanical science, in accordance with it. Her Botanic Garden and the recently developed Botanical Department in the University (which, I understand, may find its home ultimately in the Botanic Garden) will serve as centres of study of the pure science of botany. This will readily find its application to agriculture, to forestry, to economics, and in various other lines present and future. I am convinced that it is in the best interest of any State that can possibly afford to do so to encourage and endow liberally the central establishment where the pure science of botany is pursued, and to continue that encouragement and endowment, even though results of immediate practical use do not appear to be flowing from it at any given moment. For in these matters it is impossible to forecast what will and what will not be eventually of practical use. And in any case as educational centres the purely botanical establishments will always retain their important function of supplying that exact instruction, without which none can pursue with full effect a calling in the applied branches.

We may now turn from generalities to certain points of interests in your peculiar flora which happen to have engaged my personal attention. They centre round a few rare and isolated plants belonging to the Pteridophyta, a division of the vegetable kingdom which there is every reason to believe to have appeared relatively early in the history of evolution. But though the type may be an ancient one, it does not follow that every representative of it preserves the pristine features intact. Throughout the ages members of these early families may themselves have progressed. And so among them to-day we may expect to find some which preserve the ancient characters more fully than others. The former have stood still, and may be found to compare with curious exactitude with fossils even of very early date. The latter have advanced, and though still belonging to the ancient family, are by their modifications become essentially modern representatives of it. For instance, the fern Angiopteris has a sorus which very exactly matches sori from the Palæozoic period, and it may accordingly be held to be a very ancient type of fern. On the other hand, the genera Asplenium, or Polypodium, include ferns of a type which has not been recognised from early fossil-bearing rocks, and they may be held to be essentially modern. But still all of them clearly belong to the family of the Ferns.

In the Australian flora only three of the four divisions of the Pteridophyta are represented. For, curiously enough, there does not appear to be any species on your continent of the widely spread genus Equisetum, the only living genus of that great phylum of the Equisetales, which figured so largely in the Palæozoic period; and this notwithstanding that one species (*E. debile*) is present among the Polynesian Islands. But all the three other divisions of the Pteridophyta are included, and are represented in each case by plants which show peculiar and probably for the most

part archaic characters. I propose to sketch before you very briefly the points of interest which the more notable of these archaic types present. Some justification may be found for my doing so because nearly all of them have been submitted to detailed study in my laboratory in Glasgow, and much of the work has been done upon material supplied to me by your own botanists. I take this opportunity of offering to them collectively my hearty thanks.

The tenure by Dr. Treub of the office of director of the Botanic Gardens of Buitenzorg, was rendered famous by his personal investigations, and chiefly by his classical researches on the Lycopods. These were followed up by other workers, and notably by Bruchmann; so that we now possess a reasonable basis for comparison of the different types of the family as regards the prothallus and embryology, as well as of the sporophyte plant; and all these characters must be brought together as a basis for a sound conclusion as to their phyletic seriation. The most peculiar living Lycopods are certainly Isoëtes and Phylloglossum, both of which are found in Australia. The former need not be specially discussed here, as it is a practically world-wide genus. It must suffice to say that it is probably the nearest living thing to the fossils Lepidodendron and Sigillaria, and may be described as consisting of an abbreviated and partially differentiated Lepidostrobus seated upon a contracted stigmarian base.

But Phylloglossum, which is peculiar to the Australasian region, naturally claims special attention. The plant is well known to botanists as regards its external features, its annual storage tuber, its leafy shoot with protophylls and roots, and its simple shaft bearing the short strobilus of characteristic Lycopod type. But its prothallus has never been properly delineated, though it was verbally described by Dr. A. P. W. Thomas in 1901 (Proc. Roy. Soc., vol. lxix., p. 285). Perhaps the completed statement may have been reserved as a pleasant surprise for this meeting. But the description of thirteen years ago clearly shows its similarity to the type of *Lycopodium cernuum*. The sporophyte compares rather with *L. inundatum*. Both of these are species which, though probably not the most primitive of the genus, are far from being the most advanced. As all botanists know, the question of the position of Phylloglossum chiefly turns upon the view we take of the annual tuber and its protophylls. Treub, finding similar conditions in certain embryos of Lycopods, called it a "protocorm," and believed that he recognised in it an organ of archaic nature, which had played an important part in the early establishment of the sporophyte in the soil, physiologically independent of the prothallus. I must not trouble you here with the whole argument in regard to this view. Facts which profoundly affect the conclusion are those showing the inconstancy of occurrence of the organ. Mr. Holloway has recently described it as of unusual size in your native *L. laterale*, as it is also in *L. cernuum*. But it is virtually absent in those species which have a large intraprothallial foot, such as *L. clavatum*, as well as in the genus Selaginella and in Isoëtes. In *L. selago*, which on other grounds appears to be primitive, there is no "protocorm." Such facts appear to me to indicate caution. They suggest that the "protocorm" is an opportunist local swelling of inconstant occurrence, which, though biologically important in some cases, is not really primitive.

If this is the comparative conclusion, then our view will be that Phylloglossum is a type of Lycopod which has assumed, perhaps relatively recently, a very practical mode of annual growth. Related, as it appears to be on other points, with the *L. inundatum* group of species, it has bettered their mode of life. *L. inundatum* dies off each year to the very tip of its shoot, so that only the bud remains to the following season. It is notable that Goebel has described long ago how the young adventitious buds of this species start with small "protocorms," quite like those of Phylloglossum itself, or like the embryo of *L. cernuum*. And so we may conclude that in Phylloglossum a tuberous development, containing a store to start the plant in the spring, has been added to what is already seen normally each year in *L. inundatum*. And this mode of life of Phylloglossum begins, as Thomas has shown, with its embryo. This appears to me to be a rational explanation of the "protocorm" of Phylloglossum; but it robs the plant of much of its theoretical interest as an archaic form.

The phylum of the Sphenophyllales was originally based on certain slender straggling plants of the genus Sphenophyllum found in the Palæozoic Rocks; but they apparently died out in the Permian period. Your native genera, Tmesipteris and Psilatum, were ranked by earlier botanists with the Lycopods, but a better acquaintance with their details, and especially the examination of numerous specimens on the spot, indicated a nearer affinity for them with the Sphenophyllales. It was Prof. Thomas who in 1902 first suggested that the Psilotaceæ might be included with the Sphenophyllæ in the phylum of the Sphenophyllales, and I personally agree with him. Dr. Scott, however, dissents, on the ground that the leaves are persistently whorled in the sphenophylls, while they are alternate in the Psilotaceæ; and while the former branch monopodially the latter dichotomise. But since both these characters are seen to be variable within the not far distant genus Lycopodium, the differences do not seem to me to be a sufficient ground for keeping them apart as the separate phyla of Sphenophyllales and Psilotales. Whatever degree of actual relation we trace, such plants as Tmesipteris and Psilotum are certainly the nearest living representatives of the Sphenophylleæ, a fact which gives them a special distinction. The Psilotaceæ also stand alone in the fact that they are the only family of the Pteridophytes in which the gametophyte is still unknown. They produce spores freely, but there the story stops. Any young Australian who hits upon the way to induce these recalcitrant spores to germinate, and to produce prothalli and embryos, or who found their prothalli and embryos in the open, would have before him a piece of work as sensational as anything that could be suggested. Further, I am told that Tmesipteris grows here on the matted stumps of *Todea barbara*. I shall be alluding shortly to the fossil Osmundaceæ. May we not venture to fancy the possibility of some fossil Osmunda being found which has embalmed for us among its roots a Mesozoic or even a Tertiary Sphenophyll? And thus a link might be found between the Palæozoic types and the modern Psilotaceæ, not only in time, but even in character.

We pass now to the last phylum of the Pteridophyta, the Filicales. I am bound to say that for me its interest far outweighs that of the others, and for this reason: that it is represented by far the largest number of genera and species at the present day, while there is a sufficiently continuous and rich succession of fossil forms to serve as an efficient check upon our comparative conclusions.

Since 1890 it has been generally accepted that the Eusporangiate ferns (those with more bulky sporangia) were phyletically the more primitive types, and the Leptosporangiate (those with more delicate sporangia) the derivative, and in point of time later. The fossil evidence clearly upholds this conclusion. But, further, it has been shown that the character of the sporangium is merely an indicator of the general constitution of the plants in question. Where it is large and complex, as in the Eusporangiates, all the apical seg-

mentations are, as a rule, complex, and the construction of the whole plant relatively bulky. Where the sporangium is delicate and relatively simple all the apical segmentations follow suit, and the construction of the plant is on a less bulky model. On this basis we may range the ferns roughly as a sequence, starting from relatively bulky types of the distant past, and progressing to the more delicate types of the present day. The large majority of the living species belong naturally to the latter. But the former are still represented by a few genera and species which, like other survivals from a distant past, are frequently of very restricted distribution.

An interesting feature of the Australasian flora is that a considerable number of these relatively ancient forms are included in it. Thus the Marattiaceæ are represented by one species of Marattia and one of Angiopteris. Though in themselves interesting, they will be passed over without special remark, as they are very widely spread tropical forms.

All the three genera of Ophioglossaceæ are included, there being two species of Ophioglossum and two of Botrychium, while Helminthostachys is recorded from Rockingham Bay. This family is coming more than ever to the front in our comparisons, owing to their similarity in various aspects to the ancient Botryopterideæ. Though the Ophioglossaceæ have no secure or consecutive fossil history, still they may now be accepted as being very primitive but curiously specialised ferns. Perhaps the most interesting point recently detected in them is the suspensor found by Dr. Lyon in *Botrychium obliquum*, and by Dr. Lang in Helminthostachys. This provides a point for their comparison with the similar embryonic condition in Danœa, as demonstrated by Prof. Campbell. The existence of a filamentous initial stage of the embryo is thus shown for three of the most primitive of living ferns. Its existence in all of the Bryophytes, and in most of the Lycopods, as well as in the seed-plants, is a very significant fact. Dr. Lang suggests that "the suspensor represents the last trace of the filamentous juvenile stage in the development of the plant, and may have persisted in the seed-plants from their filicineous ancestry." Such a possibility would fit singularly well with the theory of encapsulation of the sporophyte in the venter of the archegonium.

The representation of the ancient family of the Osmundaceæ in the Australasian flora is very fine, though limited to five living species, while Osmunda itself is absent. It is, however, interesting that the family dates back locally to early fossil times. It was upon two specimens of Osmundites from the Jurassic Rocks in the Otago district of New Zealand that the series of remarkable papers on the fossil Osmundaceæ by Kidston and Gwynne-Vaughan was initiated. It is no exaggeration to say that these papers have done more than any other recent researches to promote a true understanding, not only of the Osmundaceæ themselves, but of fern-anatomy as a whole. They have placed the stellar theory in ferns for the first time upon a basis of comparison, checked by reference to stratigraphical sequence. It would be leading us too far for me to attempt here to summarise the important results which have sprung from the study of those fossils, so generously placed by Mr. Dunlop in the hands of those exceptionally able to turn them to account. It must suffice to say that it is now possible to trace as a fairly continuous story the steps leading from the protostelic state to the complex condition of the modern Osmunda. These facts and conclusions are to be put in relation with the anatomical data fast accumulating from the Ophioglossaceæ in the hands of Prof. Lang and others. From such comparisons a rational explanation of the evolutionary steps leading to the complex stelar state in ferns at large begins to emerge. This is no mere tissue of surmises, for the conclusions are based on detailed comparison of types occurring in lower horizons with those of the present day.

I must pass over with merely nominal mention your interesting representation of the ancient families of Schizæaceæ, Gleicheniaceæ, and Hymenophyllaceæ, all of which touch the very foundations of any phyletic system of ferns. Also the magnificent array of Dicksonieæ and Cyatheæ, and of the important genus Lindsaya—ferns which take a rather higher position in point of view of descent. But I am bound to devote a few moments to one of your most remarkable ferns, endemic in New Zealand—the monotypic Loxsoma.

This species has peculiar characters which justify its being regarded systematically as the sole representative of a distinct tribe. It is also restricted geographically to the North Island of New Zealand. These facts at once suggest that it is an ancient survival, a conclusion with which its solenostelic axis, its sorus and sporangium, and its prothallus readily accord. I have lately shown that the Leptosporangiate ferns fall into two distinct series, those in which the origin of the sorus is constantly superficial, and those in which it is as constantly marginal. Loxsoma is one of the "Marginales." It shares this position with the Schizæaceæ, Thyrsopterideæ, Hymenophyllaceæ, and Dicksonieæ, and the derivatives Davallieæ and Oleandreæ. Its nearest living relative is probably Thyrsopteris, which is again a monotypic species endemic in the island of Juan Fernandez. There is also a probable relation to the genus Loxsomopsis, represented by one species from Costa Rica, and a second lately discovered in Bolivia. Such a wide and isolated distribution of types, which by their characters are certainly archaic, suggests that we see in them the relics of a filicineous state once widely spread, which probably sprang from a Schizæaceous source, and with them represent the forerunners of the whole marginal series. If we look for further enlightenment from the fossils, it is to the Secondary rocks that we should turn. It is then specially interesting that Mr. Hamshaw Thomas has lately described a new Jurassic fern, *Stachypteris halli*, which has marginal sori, and is probably referable to a position like that of Loxsoma and Thyrsopteris, between the Schizæaceæ and the Dicksonieæ. In fact, the gaps in the evolutionary series of the Marginales are filling up. We may await with confidence fresh evidence from the Jurassic period, upon which Prof. Seward is directing an intensive interest.

I should be ungrateful indeed if I did not mention your very full representation of Blechnoid ferns: for developmental material of several of these has been sent to me by Dr. Cockayne, and others from New Zealand. A wide comparative study of the genus has led me to somewhat unexpected results in regard to the plasticity of the sorus, its phyletic fusions and disruptions. The consequent derivative forms are seen in Woodwardia and Doodya on one hand, and on the other in Scolopendrium and Asplenum. These ferns together constitute a coherent phylum springing ultimately from a Cyatheoid source. The details upon which this conclusion is based I hope to describe in a separate communication to the section.

And, lastly, the Hydropterideæ deserve brief mention. Represented in your flora by two species of Azolla, and one each of Marsilea and Pilularia, they typify a condition which must theoretically have existed among ferns in very early times, viz., the heterosporous state. But hitherto, notwithstanding the existence of our living Hydropterideæ, no fossil fern with microscopic structure preserved had been detected from the primary rocks, showing this intermediate condition between the homosporous type and that of

the pteridosperms. This unsatisfactory position has now been resolved by Professor Lignier, who has recently described, under the name of Mittagia, a fossil from the Lower Westphalian, which bore sori of which the sporangia contained four megaspores, while the outer tissues of the sporangia resembled those of Lagenostoma. Pending the discovery of further specimens, these observations may be welcomed as filling with all probability a conspicuous gap in the evolutionary sequence of known forms.

From the rapid survey which I have been able to give you of some of the more notable Australasian ferns of relatively archaic type, it is clear that they have a very interesting and direct bearing upon the phylesis of ferns. The basis upon which conclusions as to phyletic sequence are arrived at is at root that of the natural system of classification generally—the recognition, not of one character, or of two, but of as many as possible, which shall collectively serve as criteria of comparison. In the case of the Filicales we may use the characters of :—

(i) External form.
(ii) Constitution, as shown by simple or complex segmentation.
(iii) Dermal appendages, hairs or scales.
(iv) Stelar structure, simple or complex.
(v) Leaf-trace, coherent or divided.
(vi) Soral position.
(vii) Soral construction.
(viii) Indusial protections.
(ix) Sporangial structure, and mechanism of dehiscence.
(x) Spore-output.
(xi) Spore-form, and character of wall.
(xii) Form of prothallus.
(xiii) Position of the sexual organs, sunken or superficial.
(xiv) Number of spermatocytes, and method of dehiscence.
(xv) Embryology.

In respect of all these criteria progressions of character may be traced as illustrated by known ferns, and probably other criteria may emerge as study progresses. In each case, upon a footing of general comparison, checked as opportunity offers by reference to the stratigraphical sequence of the fossils, it may be possible to distinguish with some degree of certainty what is relatively primitive from what is relatively advanced. Thus, the protostele is generally admitted to be more primitive than the dictyostele, the simple hair than the flattened scale, and a high spore-output than a low one.

Applying the conclusions thus arrived at in respect of the several criteria, it becomes possible upon the sum of them to lay out the species and genera of ferns themselves in series, from the primitive to the advanced. In proportion as the progressions on the basis of the several criteria run parallel, we derive increased assurance of the rectitude of the phyletic sequences thus traced, which may finally be clinched, as opportunity offers, by reference to the stratigraphical occurrence of the corresponding fossils. This is in brief the phyletic method, as it may be applied to ferns. It may with suitable variation be applied to any large group of organisms, though it is seldom that the opportunities for such observation and argument are in any sense commensurate with the requirements. Perhaps there is no group of plants in which the opportunities are at the moment so great as in the Filicales, and they are yielding highly probable results from its application.

The greatest obstacle to success is found in the prevalence of parallel development in phyla which are believed to have been of distinct origin. This is exemplified very freely in the ferns, and the systematist has frequently been taken in by the resemblances which result from it. He has grouped the plants which show certain common characters together as members of a single genus. Sir William Hooker in doing this merged many genera of earlier writers. His avowed object was not so much to secure natural affinity in his system as readiness of identification: and consequently in the "Synopsis Filicum" there are nominal genera which are not genera in the phyletic sense at all. For instance, Polypodium and Acrostichum, as there defined, may be held from a phyletic point of view to be collective groupings of all such ferns as have attained a certain state of development of their sorus; and that they are not true genera in the sense of being associated by any kinship of descent: this is shown by the collective characters of the plants as a whole. Already at least four different phyletic sources of the Acrostichoid condition have been recognised, and probably the sources of the Polypodioid condition are no fewer. Such "genera" represent the results of a phyletic drift, which may have affected similarly a plurality of lines of descent. It will be the province of the systematist who aims at a true grouping according to descent to comb out these aggregations of species into their true relationships. This is to be done by the use of wider, and it may be quite new, criteria of comparison. Advances are being made in this direction, but we are only as yet at the beginning of the construction of a true phyletic grouping of the Filicales. The more primitive lines are becoming clearer: but the difficulty will be greatest with the distal branches of the tree. For these represent essentially the modern forms, they comprise the largest number of apparently similar species, and in them parallel development has been most prevalent.

If this difficulty be found in such a group as the Filicales, in which the earlier steps are so clearly indicated by the related fossils, what are we to say for the Angiosperms? Our knowledge of their fossil progenitors is very fragmentary. But they are represented now by a multitude of forms, showing in most of their features an irritating sameness. For instance, vascular anatomy, that great resource of phyletic study in the more primitive types, has sunk in the Angiosperms to something like a dead level of uniformity. There is little variety found in the contents of embryo-sacs, in the details of fertilisation, or in embryology. Even the ontogeny as shown in the seedling stages affords little consolation to the seeker after recapitulation. On the other hand, within what are clearly natural circles of affinity there is evidence of an extraordinary readiness of adaptability in form and structure. Such conditions suggest that we see on one hand the far-reaching results of parallel development, and on the other the effects of great plasticity at the present day, or in relatively recent times. Both of these are points which prevent the ready tracing of phyletic lines. In the absence of trustworthy suggestions from palæontology, the natural consequence is the current state of uncertainty as to the phyletic relations of the Angiosperms.

Various attempts have been or are being made to meet the difficulty. Some, on the basis of the recent observations of Wieland and others, are attempting along more or less definite monophyletic lines to construct, rather by forcible deduction than by any scientific method of induction, an evolutionary story of the Angiosperms. I do not anticipate that any great measure of success, beyond what is shown in a very polysyllabic terminology, and an appearance of knowing more than the facts can quite justify, will attend such efforts. It would seem to me to be more in accord with the dictates of true science to proceed

in a different way, as indeed many workers have already been doing. To start, not from preconceptions based upon limited palæontological data, but from an intensive study of the living plants themselves. To widen so far as possible the criteria of comparison, by making, for instance, every possible use of cellular, physiologico-chemical, and especially secretory detail, and of minor formal features, such as the dermal appendages, or by initiating a new developmental morphology of the flower from the point of view of its function as a whole: and with its physiological end clearly in sight, viz. the maturing, nourishing, and placing of new germs. To make on some such basis intra-ordinal, and intra-generic comparisons with a view to the phyletic seriation of closely related forms; and so to construct probable short series, which may subsequently be associated into larger phyletic groupings. This should be checked wherever possible by physiological probability. A keen eye should be kept upon such information as geographical distribution and palæontology may afford, and especially upon the fossils of the Mesozoic period. What is above all needed for success among the Angiosperms is new criteria of comparison, to meet the far-reaching difficulties that follow from parallel development and recent adaptation. If some such methods be adopted, and strenuously pressed forward, the task should not appear hopeless, though it cannot be anything else than an arduous one.

I cannot conclude without some remark on the bearing of parallel or convergent development, so fully exemplified in the Filicales, upon the question of the genesis of new forms. Anyone who examines, from the point of view suggested in this address, the larger and well-represented divisions of the Vegetable Kingdom must be impressed with the extraordinary dead level of type to which their representatives have attained. In most of these divisions the phyletic history is obscured, partly by the absence of any consecutive palæontological record, but chiefly by the want of recognised criteria for their comparison. This is very prominently the case for the Mosses, and the Angiosperms.

But it may be doubted whether these large groups differ in any essential point, in respect of the genesis of their multitudinous similar forms, from the Filicales, in which the lines of descent are becoming clearer through additional knowledge. Suppose that we knew of no fossil Ferns; and that none of the early fern-types included under the term "Simplices" had survived in our living flora: and that the Filicales of our study consisted only of the 2500 living species of the old undivided genera of Polypodium, Asplenium, Aspidium, and Acrostichum. Then the phyletic problem of the Filicales would appear as obscure as does that of the Mosses, or of the Angiosperms of the present day. They would present, as these great groups now do, an apparent dead level of sameness in type, though the phyletic starting-points in each may have been several and distinct. There is every reason to suppose that in the phylesis of the Mosses or the Angiosperms also there has been a parallel, and even a convergent, development of the same nature as that which can be cogently traced in the Filicales: but that it is obscured by the obliteration of the early stages. Internal evidence from their comparative study fully justifies this conclusion. How, then, are we to regard this insistent problem of parallelism and convergence from the point of view of genetic study?

A belief in the "inheritance of acquired characters," or, as is sometimes expressed, "somatic inheritance," is at present out of fashion in some quarters. But though powerful voices may seem to have forced it for the moment into the background, I would take leave to point out that such inheritance has not been disproved. All that has been done, so far as I understand the position, is to show that the evidence hitherto advanced in support of it is insufficient for a positive demonstration. That is a very different thing from proving the negative. We hear of "fluctuating variations" as distinct from "mutations"; and it is asserted that the former are somatic, and are not inherited, while the latter are inherited. This may be held as a useful terminological distinction, in so far as it accentuates a difference in the heritable quality. But it leaves the question of the origin of these heritable "mutations" quite open. At the present moment I believe that actual knowledge on this point is very like a complete blank. Further, it leaves indefinite the relative extent and proportion of the "mutations." It is commonly held that mutations are considerable deviations from type I am not aware that there is any sufficient ground for such a view. It may probably have originated from the fact that the largest are most readily observed and recognised as reappearing in the offspring. But this is no justification for ignoring the possibility of all grades of size or importance of heritable deviations from type.

On the other hand, adaptation, with its consequence of parallel or even convergent development in distinct stocks, is an insistent problem. The real question is: What causes are at work to produce such results? They are usually set down to the selection of favourable divergences from type out of those produced at random. But the prevalence of parallelism and convergence suggests that those inheritable variations, which are now styled "mutations," are not produced at random. These facts enforce the question whether or not they are promoted and actually determined in their direction, or their number, or their quality, in some way, by the external conditions. Parallelism and convergence in phyletic lines which are certainly distinct impress the probability that they are. Until the contrary is proved it would, in my opinion, be wiser to entertain some such view as a working hypothesis than positively to deny it. Such a working hypothesis as this is not exactly the same as a "mnemic theory," though it is closely akin to it. It may perhaps be regarded as the morphologist's presentation, while the mnemic theory is rather that of the physiologist. But the underlying idea is the same, viz. that the impress of external circumstance cannot properly be ruled out in the genesis of inheritable characters, simply because up to the present date no definite case of inheritance of observable characters acquired in the individual lifetime has been demonstrated. Of course, I am aware that to many this is flat heresy. At this meeting of the Association it amounts almost to high treason. I plead guilty to this heresy, which may by any sudden turn of observation be transformed into the true faith. I share it in whole or in part with many botanists, with men who have lived their lives in the atmosphere of experiment and observation found in large botanic gardens, and not least with a former President of the British Association, viz. Sir Francis Darwin.

It is noteworthy how large a number of botanists dissent from any absolute negation of the influence of the environment upon the genesis of heritable characters. Partly this may be due to a sense of the want of cogency of the argument that the insufficiency of the positive evidence hitherto adduced justifies the full negative statement. But I think it finds its real origin in the fact that in plants the generative cells are not segregated early from the somatic. In this respect they differ widely from that early segregation

of germ-cells in the animal body, to which Weismann attached so much importance. The fact is that the constitution of the higher plants and of the higher animals is in this, as in many other points, radically different, and arguments from one to the other are dangerous in the extreme. Those who interest themselves in evolutionary questions do not, I think, sufficiently realise that the utmost that can be claimed is analogy between the higher terms of the two kingdoms. Their phyletic separation certainly dates from a period prior to that of which we have any knowledge from the fossil record. Let us give full weight to this fact, as important as it is indisputable. The early definition of germ-cells in the animal body will then count for nothing in the evolutionary problem of plants. Moreover, we shall realise that the plant, with its late segregation of germ-cells, will present the better field for the inquiry whether, and how far, the environment may influence or induce divergences from type. From this point of view the wide-spread opinion among botanists that the environment in some sense determines the origin and nature of divergences from type in plants should command a special interest and attention.

I must now draw to a close. I have passed in review some of your more notable plants, and pointed out how the Australasian flora, whether living or fossil, includes in unusual richness those evidences upon which the fabric of evolutionary history is being based. I have indicated how this history in certain groups is showing ever more and more evidence of parallel development, and that such development, or convergence, presses upon us the inquiry into the methods of evolutionary progress. The illustrations I have brought forward in this address clearly show how important is the positive knowledge derived from the fossils in checking or confirming our decisions. Palæophytology is to be prized not as a separate science, as, with an enthusiastic view restricted between blinkers, a recent writer has endeavoured to enforce. To treat it so would be to degrade it into a mere side alley of study, instead of holding it to be the most positive line that we possess in the broad avenue of botanical phylesis. An appreciation of such direct historical evidence is no new idea. Something of the same sort was felt by Shakespeare three centuries ago, and it remains the same to-day. Nay, more: it may lead us even to forecast future possibilities. In following our evolutionary quest in this spirit we shall find that we are indeed—

> "Figuring the nature of the times deceased

> (King Henry IV., Part II, Act iii., Scene i.)

THE WIDMANSTATTEN STRUCTURE IN VARIOUS ALLOYS AND METALS.[1]

THE surface of meteoric iron after polishing and etching in the way usually adopted, prior to examination under the microscope, shows characteristic figures which are for the most part triangles or parallelograms. These figures were observed for the first time in 1808 by M. Alois de Widmanstätten, the director of the Imperial Porcelain Works at Vienna on the Ilraschina meteorite, and although Widmanstätten himself had published nothing regarding his discoveries, a knowledge of them spread very quickly, and what he had seen were soon universally known under the name of "Widmanstätten figures." It was then generally considered that these figures were characteristic of meteoric iron and that they were not found in terrestrial iron. Guillet-Laumont[2] in 1813 already saw an analogy between the two varieties of iron; but the majority of investigators for a long time were of a different opinion, and the views of Guillet-Laumont were forgotten.

FIG. 1.—Widmanstätten Structure in Carbon Steel (Carbon 0·55 per cent.). Alloy No. 8. Magnified 8 diameters.

The interest in meteorites shown by Dr. Sorby, the founder of the science of metallography, and especially the brilliant researches of Osmond, led anew to attention being directed to the figures of Widmanstätten. Thus it was that in 1900 M. Osmond announced the discovery in the head of a steel ingot of equilateral triangles which recalled, he said, "the figures of Wid-

[1] Paper presented to the Institute of Metals for the September meeting by Capt. N. T. Belaiew (Michael Artillery Academy, Petrograd). Translated from the French of the original MS. of Capt. Belaiew, and, in consequence of the European War, not since revised by him.

[2] Cohen, *Meteoritenkunde*, 1894, vol. i., p 41.

manstätten, which are known to belong to the regular octahedral system."[3]

In a previous paper[4] the author described a steel containing 0·55 per cent. of carbon, prepared in 1908 at the works of Igewsky in accordance with the directions of the author. This steel showed throughout its mass beautiful Widmanstätten figures, which were so developed that they were perfectly visible to the naked eye (Fig. 1). The analogy between the structure of the alloy and that of the meteorites was so close that the author considers that it may be regarded as a synthetic production of a meteoritic structure, and that it is fair to refer to this structure as the Widmanstätten structure (Figs. 2 and 3).

Not only could the meteoritic structure be henceforth artificially reproduced at will, but the crystallisation of iron as well as its crystallography could be easily studied from such examples.

Although the question of the conditions which led to the appearance of this structure seemed extremely interesting, nevertheless it was considered wise to leave it on one side for the moment and to commence with what might be termed a more or less detailed "morphological" examination. From this it was not difficult to see that the character of the Widmanstätten figures changed several times in a given area, sometimes showing triangles, sometimes squares, but they are precisely the figures that would be expected in different sections of a regular octahedron the four systems of cleavages of which were parallel to the four pairs of its surfaces, an arrangement known for a long time in the case of meteorites.[5] Thus it was the octahedral crystallisation of iron which was made manifest by the distribution of the structural elements between the cleavage planes during the recrystallisation.[6] The octahedral crystallisation of alloys of iron is generally admitted,[7] and the greater part of the iron-carbon diagram belongs to the type of diagrams

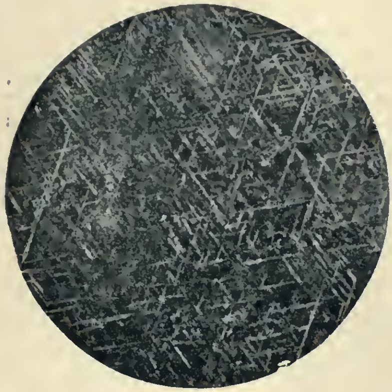

FIG. 2.—Widmanstätten Structure in Taze-well Meteorite. Section parallel to the Surface of the Octahedron. Magnified 6 diameters and slightly reduced.

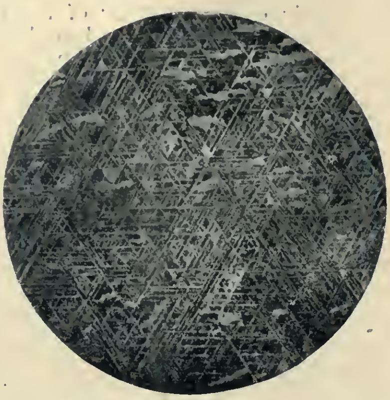

FIG. 3.—Widmanstätten Structure in Carbon Steel (Carbon, 0·55 per cent.). Alloy No. 8. Magnified 9 diameters and slightly reduced.

FIG. 4.—Swedish Iron heated to the point of Incipient Fusion (Osmond, "Sur la Cristallographie du Fer"). Magnified 16 diameters.

FIG. 5.—Widmanstätten Structure in Bronze, containing 55·1 per cent. Copper. Cooled in Sand and Annealed (L. Guillet, "Les Laitons au Nickel"). Magnified 30 diameters and slightly reduced.

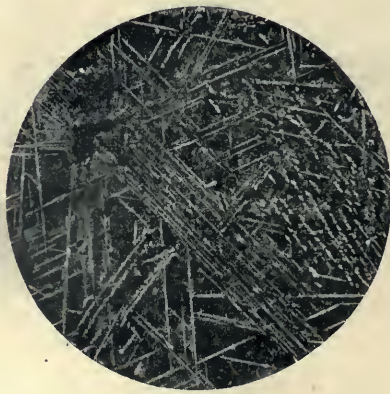

FIG. 6.—Widmanstätten Structure in Alloy of 90 per cent. Platinum and 10 per cent. Aluminium (Chouriguine, "Sur les alliages du Platine avec l'Aluminium"). Magnified 50 diameters and slightly reduced.

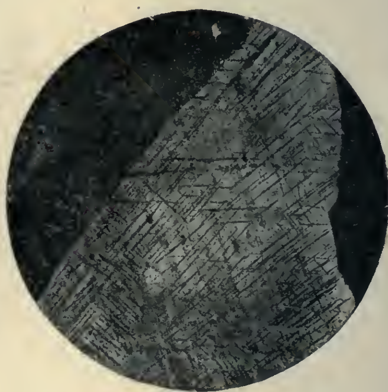

FIG. 7.—Widmanstätten Structure in Zinc, cast and cooled slowly (G. Timothéeff). Magnified (?) diameters and slightly reduced.

[3] "Sur la Cristallographie du Fer," Paris, 1900, p. 24, figs. 24 and 25. The same observation was made in 1905 by Profs. Arnold and McWilliam in their memoir, "The Thermal Transformation of Carbon Steel," Journ. of the Iron and Steel Institute, 1905, No. II., p. 35.

[5] See Figs 7, 8, 9, 10, 11, 12, and 13, in the previously mentioned paper they are also reproduced in M. Sauveur's book, "The Metallography of Iron and Steel," Lesson x., figs. 7–13.

[6] "When a liquid or solid deposits successively several solid phases, the secondary and tertiary deposits often preferentially lodge between certain of the cleavage planes (plans cristallographiques) of the primary deposit, and thus illustrate its structure." "Sur la Cristallisation du Fer," Osmond et Cartaud, *Revue de Métallurgie*, 1906, p. 658.—*Note by* Editor, Proc. Inst. of Metals.

[7] See also "Sur la crystallisation et structure des aciers refroidis lentement," N. T. Belaiew, *Revue de Métallurgie*, 1912, p. 321.

in which there is recrystallisation in the solid state.

Following the brilliant theory of Osmond, the alloys of iron and of nickel in the case of meteorites ought to follow an analogous diagram.

Not long since this theory was entirely confirmed by the beautiful experiments of Benedicks. We see that in the two cases, in that of meteorites as well as in that of terrestrial iron, the appearance of these Widmanstätten figures is connected with two fundamental facts—the character of the primary octahedral crystallisation, and the separation of the solid solution into different phases during recrystallisation.

This structure, therefore, is not in the least confined to iron and its alloys; it might be equally well encountered in each alloy or each metal which crystallises in the regular system, and in which, after solidification, the crystallised solid solution throws out secondary deposits, that is to say, is subject to recrystallisation. In a pure metal there would be an allotropic change in the solid state, as, for example, the iron shown in Fig. 4—in an alloy, the separation of a new phase; and as diagrams of this kind are well known, it ought not to be at all difficult to find examples of the Widmanstätten structure in alloys other than iron.

To this class of alloys belong, for example, the different alloys of copper, particularly the brasses and bronzes. Gulliver, in his interesting volume on metallic alloys,[8] gives numerous examples of this, mentioning the separation of $SnCu_3$ in the alloys of copper and tin, of $SbCu_2$ in those of copper and antimony, of the constituent beta in brasses with about 35 per cent. of zinc (see Gulliver, Fig. 200), or of delta in the alloys with 70 to 75 per cent. of zinc (see Gulliver, Figs. 205 and 206). The author is able to reproduce here a photograph (Fig. 5) of a brass containing 55·1 per cent. of copper (cooled in sand and annealed), which was kindly sent to him by M. L. Guillet. This photograph has great interest, as it shows the action of reheating on the Widmanstätten structure.

Fig. 6 serves as another example of this structure, for which the author is indebted to M. Chouriguine; it represents an alloy of platinum-aluminium. M. Chouriguine,[9] in studying these alloys, found a transformation in the solid state, and this transformation manifested itself in a very marked Widmanstätten structure.

It is perhaps useful to remark that the first condition, that is to say, the primary octahedral crystallisation, is not difficult to find, for the majority of metals and alloys crystallise either in the regular or in the hexagonal system. In the last case the character of the Widmanstätten figures may differ in detail whilst preserving the same general aspect, as can be seen from Fig. 7,[10] representing a sample of zinc after melting and slow cooling.

These few examples, though taken somewhat haphazard, serve nevertheless as illustrations of the great extent to which the Widmanstätten structure exists in different alloys and metals. In the alloys of iron the Widmanstätten structure has an important industrial interest, as it gives rise to very poor mechanical properties in the case of cast steels and in overheated steels.

The chief object of this brief communication is to direct the attention of metallurgists and engineers to the study of alloys, other than iron, from the point of view of the production and the removal of the Widmanstätten structure.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Belfast.—Prof. R. H. Yapp has been appointed professor of botany in the Queen's University, Mr. C. W. Valentine professor of education, and Sir Hiram Shaw Wilkinson pro-Chancellor of the University.

Glasgow.—Dr. W. J. Dilling, of Aberdeen, has been appointed to the new "Robert Pollok" lectureship, for research in materia medica and pharmacology, at the University of Glasgow.

The University Court has given leave of absence to Mr. A. Stevens, assistant in the department of geography, in order that he may accompany Sir Ernest Shackleton's Antarctic Expedition as geologist. The Court has also placed at his disposal a petrological microscopic equipment for the purposes of the expedition.

Temporary arrangement have been made for carrying on the work of a considerable number of the lecturers, assistants, and examiners, who, in consequence of the war, are absent on duty or detained abroad.

Dr. D. A. Campbell, of Halifax, has, says *Science*, promised 12,000*l*. to endow a chair of anatomy at Dalhousie University, Halifax, in memory of his son, the late Dr. George Campbell.

The council of the Senate of the University of Cambridge has offered to professors, teachers, and students of the University of Louvain such facilities in the way of access to libraries, laboratories, and lectures, together with the use of lecture-rooms, as may secure the continuity of the work of that University during the present crisis. Hospitality in the way of living accommodation and so forth will probably be offered by the individual colleges and by private residents. The professors of the University of Oxford have offered a home for the winter to the young children of the professors of the University of Louvain; and the academic staff of University College (University of London) offers hospitality to about seventy members of French and Belgian universities, whether professors, teachers, or students, men or women, who may find it necessary to take refuge in this country.

A well illustrated prospectus for the present session of the Municipal Technical Institute, Belfast, has been issued. The chief object of the institute is to provide instruction in the principles of the arts and sciences which bear upon the trades and industries of Belfast, and to show by experiment how these principles may be applied to their advancement. The evening classes are designed for persons engaged during the day in handicrafts or business who desire to supplement and develop the knowledge and experience they have gained in the workshop and warehouse. It is satisfactory to notice that the prospectus insists that the successful prosecution of special studies is in proportion to the student's knowledge at the beginning of such work of the elements of mathematics and drawing. The day technical course provides instruction in the science and technology of mechanical and electrial engineering, the textile industries, and pure and applied chemistry; and it gives a sound training to youths who aim at filling responsible positions in these departments of activity. We notice that the Queen's University of Belfast and the Belfast Corporation have entered into an agreement whereby the institute is recognised as a college in which students of the University may study to qualify for a degree or diploma in science of the University. It is impossible in view of the completeness and multiplicity of the arrangements which have been made to meet the needs of every class of student, to mention them all, but attention

may be directed to the public textile testing and conditioning house which has been opened at the institute. This house examines textile materials with the object of ascertaining and certifying their true length, weight, condition, and strength; and of carrying out other investigations required by merchants and manufacturers.

The Northampton Polytechnic Institute, London, E.C., has issued its "Announcements Educational and Social for the Session, 1914–15." The announcements form a volume of 298 pages, and give full particulars of a varied and comprehensive curriculum. The work of the institute is divided into two main sections: an educational section for technological subjects, and a social and recreative section. The educational aim is to provide classes in technological and trade subjects, special attention being directed to the immediate requirements of Clerkenwell, the district in which the polytechnic is situated. Prominent among the day courses is that provided in technical optics. The aim in this department is to provide the thorough theoretical and practical training now required in various branches of the optical industry. It is believed that there is now, and that there will be for some time to come, a considerable demand for well-trained men. In connection with the practical side of this training the department has had the benefit of advice and assistance from prominent members of the optical trade. The full course as at present established extends over two years, and is divided into two sections, for opticians and optical instrument makers respectively. The engineering day college is organised in two departments for civil and mechanical engineering, on one hand, and for electrical engineering on the other. In the former arrangements have been made for the teaching of aeronautical engineering. The course in aeronautical engineering will follow the same plan as the other engineering day courses, that is, the first two years will be devoted to the subjects which form the ground work of all engineering, and the necessary specialisation will take place in the third and fourth years. These are a few examples of the practical character of the instruction given, and a reference only is possible to some of the other courses, which include watch- and clock-making and horological engineering generally, many branches of technical chemistry, and subjects connected with the jewelry, silversmiths', and metal-working trades. Evening classes on an even more comprehensive plan have also been arranged.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 7.—M. P. Appell in the chair.—G. **Bigourdan**: Observations of the Delavan comet (1913*f*) made at the Paris Observatory. Positions given for September 2 and 3. The comet was visible to the naked eye in spite of the size of the moon. It appeared to be of the fifth magnitude.—M. **Appell**: A transformation of certain functions deduced from Θ functions of higher degree.—L. **Mangin**: The polymorphism of certain diatoms from the Antarctic. It is shown that the classification of diatoms by the markings or values is faulty, since these show for a given species much less fixity than the structure of the endochrome. The paper is accompanied by numerous illustrations.—M. **Fournier**: The resistance of a fluid to the horizontal translation of a spindle-shaped body, moving in the line of the axis of the figure.—P. **Gaubert**: The faces of solution of dolomite. A study of the relations between the crystalline symmetry and etching figures produced by the action of very dilute nitric or hydrochloric acids.

PONIES, PHEASANTS, AND POULTRY.

(1) *The Shetland Pony.* By Charles and Anne Douglas. With an Appendix on "The Making of the Shetland Pony." By Prof. J. Cossar Ewart. Pp. xi+176+plates. (Edinburgh and London: W. Blackwood and Sons, 1913.) Price 10*s*. 6*d*. net.

(2) *Pheasants and Covert Shooting.* By Captain A. Maxwell. Pp. ix+332+plates. (London: A. and C. Black, 1913.) Price 7*s*. 6*d*. net.

(3) *Our Domestic Birds.* Elementary Lessons in Aviculture. By John H. Robinson. Pp. x+317. (Boston and London: Ginn and Co.) Price 6*s*.

(1) IT was a happy thought on Mr. and Mrs. Douglas's part to write the story of the Shetland pony—a survivor of the race of small horses which was established in Britain in very early times. The winsome creature, "small, robust, gay, shaggy, alert, strong of bone, short-eared, large-eyed," may be a composite of Oriental and Scandinavian virtues, but there has been for long a definite unified race, well adapted to the natural conditions and human needs in Shetland. Sheltered by abundant mane and tail and "that waterproof double coat of thick fur and long hair which alone can maintain warmth in wind and rain and mist"; endowed with endurance and "metall past belief"; yet with "docility and sweetness of temper which make it more truly domestic than any other horse," the Shetland pony is congruent with its home. The authors have written of it with pleasure, and their book is naturally therefore pleasant reading. They tell us of the history of the modern Shetland pony, which owes much to the stud established by the Marquis of Londonderry in 1870, and much to a single individual called Jack. They describe the points of the best type, and suggest lines of progress and improvement. There is a valuable chapter on management, evidently based on long experience. The book is finely illustrated with interesting photographs.

We cannot refrain from quoting the delightful closing paragraph of a charming book on a charming subject.

"Yet in the end it is idle to deny that it is not his indisputable economic validity that binds the Sheltie's lovers to him: rather it is himself, his wisdom and his courage, his companionable ways, his gay and willing service. Having taken from him their first falls and first riding lessons, and fought with him their first battles, they look forward to an old age in which he shall draw their bath-chairs; and in the interval of life he provides as a field animal the dual charm of a creature at once wild and tame—wild in his strong instincts, his hardihood, and his independence—domestic in his wisdom and sweet temper, his friendly confidence in mankind, and his subtle powers of ingratiation."

Prof. J. Cossar Ewart has added to the value of the book by furnishing a zoological appendix on "The Making of the Shetland Pony." He comes to the conclusion that—

"Shetland ponies are mainly descended from the 'small and fleet' race yoked to the chariots of the Caledonians at the battle of Mons Graupius. This ancient race, again, was probably to begin with a blend of the slender-limbed, Arab-like ponies of the Swiss lake-dwellers, and of a thick-set race of the elephant-bed type."

As to the small size, he says:

"If Shetland ponies have not sprung from a small wild pigmy race, it may be safely asserted that their small size is mainly due to isolation in small areas where they were forced to shift for themselves under, as a rule, extremely unfavourable conditions."

(2) Captain Aymer Maxwell has written an admirable book on "Pheasants," a welcome companion to his well-known "Partridge." It is marked by competence of information, carefulness of statement, a vigorous, interesting style, and sound judgment on vexed questions. It is embellished by numerous charming coloured pictures by Mr. George Rankine. Most of the chapters are of course practical, dealing with the rearing of birds, the care of coverts, the shooting, the inevitable conflict of interests between fox-hunting and pheasant-preserving, and similar subjects. In connection with covert-shooting, the duck comes in for a chapter. The first three chapters of the book are devoted to questions of natural history—the different kinds of pheasants, their habits, and their history. The Colchican pheasant, now uncommon in Britain, was introduced by persons unknown before 1000 A.D., and remained in undisturbed possession until the end of the eighteenth century, when the ring-necked species was introduced from Southern China. Thereafter came Japanese pheasants, Mongolian pheasants, and more besides; and as most of them interbreed freely, our "common pheasant" is a vigorous mongrel which may combine characters of four or five species. The author has interesting notes on many subjects: the wild traits persisting in reared pheasants, the rate of flight—rather under forty miles an hour, the power of swimming, the cock's dangerous custom of proclaiming where he settles down for the night, the pheasant vocabulary, the courtship, the suppression of scent when

the hen-pheasant is sitting, the miscellaneous diet, the assumption of male plumage by hens, the crossing with capercailzie, blackgame, guinea-fowl, and poultry. We are not forgetting that this is not the first book on the pheasant, but it is written with freshness and first-hand knowledge, and should enjoy a deserved popularity.

(3) We are much behind the times in Britain as regards aviculture, and it is to be hoped that Mr. John H. Robinson's very competent book will serve as a stimulus. It has been computed that the annual production of poultry in the United States approaches the value of a thousand million dollars, and Mr. Robinson shows that there is pleasure as well as profit in the business. We do not think that anyone can read his book without wishing more power to the elbow of those who have been active in recent years in increasing and improving poultry-keeping in this country. It should be noted that Mr. Robinson's book is actually meant for schools, and that he defends this on educational as well as on utilitarian grounds. His enthusiasm is not damped by any thought of the danger, probably in great part a bogey, of tethering school-children too early to the practical problems of life. A second book of a purely technical character is, we understand, being prepared; the object of this one is:

> "To tell in plain language the things that everyone ought to know about poultry, pigeons, and cage birds; to teach fundamental facts in such a way that they will be fixed in the mind; to excite interest in the subject where none existed; and to direct enthusiasm along right lines."

Mr. Robinson is not afraid of what his fellow-countrymen sometimes call "hen-fever."

The book deals in a robust practical way with fowls, ducks, geese, turkeys, guinea-fowls, pea-fowls, pheasants, swans, ostriches, pigeons, and canaries and it seems to us to fulfil its purpose. Our only suggestion is that, before a second edition is printed, the author should get some zoological friend to read over the general introduction, which is not without blemish. If aviculture is to be a school-subject, its presentation should be scrupulously accurate. Therefore, some changes should be made in statements such as the following: "Many insects and one species of mammal (the bat) fly." "Man learned melody from the song birds." "These yolks are not germs, but as they grow the germ forms on one side of each yolk, where it appears as a small white spot." These are merely examples of different kinds of statements which admit of improvement. On page 35 it is indicated that the theory of the origin of domestic fowl from the Indian jungle fowl is no longer tenable, but we would refer the author to a well-known American ornithologist, Mr. C. W. Beebe, who wrote in April of this year: "I can find no reason to attribute the ancestry of all varieties of our domestic fowls to other than the red jungle fowl of India, *Gallus Gallus* (Linnæus)." We have not observed any reference to Mendelism in Mr. Robinson's book, but we suppose the omission must be deliberate. If so, one would like to know why.

SILICA AND SILICATES

La Silice et les Silicates. By Henry Le Chatelier. Pp. 574. (Paris: A. Hermann et Fils, 1914.) Price 15 francs.

SILICA, as is well known, constitutes a large proportion of the earth's crust, and in some form or other plays a very important part in commerce and industry. Silica and silicates are largely used as material for building purposes, for pottery, glass, cement, fluxes, etc. Their full importance is perhaps not brought out in the ordinary text-books; comparatively little is said about them in most books on chemistry and, on the other hand, while in treatises on mineralogy a considerable proportion of the pages are devoted to this large mineral group in their scientific aspect, their practical applications are almost wholly ignored. Prof. Le Chatelier's work is therefore very welcome, especially since it is from the pen of one who has himself done so much to extend our knowledge of the physical properties of the products of these materials.

After a short introduction, in which he epitomises the scope of the book, the author enters into a full description of the characters of the anhydrous and hydrous forms of silica, typified respectively by quartz and chalcedony, and by opal; the rare tridymite and cristobalite are, however, also discussed. Apart from jewelry, quartz is invaluable in saccharimetry and microscopy, and in recent years an extremely important use has been discovered for it in its amorphous form. The excellence of quartz fibres for torsional purposes was pointed out by Boys a quarter of a century ago, and his ingenious method of preparing them has never been improved upon. For vessels likely to be subjected to rapid and considerable changes of temperature amorphous quartz far surpasses glass, and finds extensive use at the present day. Next in a series of five chapters the properties and peculiarities of the principal different varieties of glass are fully discussed.

The various silicates are described in the following series of chapters, but the characters of

most of the species are only summarised briefly, greater space being allotted to those of commercial importance. Considerable attention is, of course, given to china-clay, and this chapter paves the way for an important one on pottery. Incidentally in these chapters many questions of scientific importance are discussed; for instance, solid solutions, mixed crystals, hydrated salts, and the classification of the silicates; Prof. Le Chatelier himself adopts in this book a chemical classification. The admirable work done at the Geophysical Laboratory, Washington, on the artificial production of certain groups of silicates and the determination of their properties, receives adequate treatment. In the concluding chapter the author reviews very briefly the principal rocks and their classification, and the fluxes.

The book is well printed, but, like French books in general, is issued unbound and with uncut leaves. It unfortunately lacks an index.

NEW BOOKS ON CHEMISTRY.

(1) *Modern Steel Analysis.* By J. A. Pickard. Pp. viii+128. (London: J. and A. Churchill, 1914.) Price 3*s.* 6*d.* net.

(6) *De la Pirotechnia* (1540). By V. Biringuccio. A Cura e con Introduzione di A. Mieli. Vol. i. Pp. lxxxv+198. (Bari: Società Tipografica Editrice Barese, 1914.) Price 3 lire.

(1) THE little volume by J. A. Pickard is one which may be safely recommended to those who are engaged in iron and steel analysis. The introductory chapter might indeed be read with advantage by any analytical chemist whatever his speciality. The sodium bismuthate method for the estimation of manganese is fully described, and the volumetric methods for the estimation of phosphorus, nickel, and chromium, in short, the various processes, so far as the writer can judge, are well up-to-date. It may be observed that the author does not mention the use of porcelain funnels or Gooch crucibles, but recommends pulp filters laid over perforated discs in ordinary funnels. It is impossible to say without experience what advantage the pulp filter has over well-fitting paper discs in a small Buchner funnel, but from the description the former seems the more troublesome arrangement. No reference is made to the moist combustion method described many years ago by Turner in which the carbon was filtered through asbestos and ignited sand contained in a hard glass tube and burnt *in situ*; for Turner's method seems more convenient and accurate than the process described here, involving the transference of the carbon and filter to the combustion tube.

(2) The rapidly increasing use of metals in organic synthesis in recent years has expanded the literature to such dimensions that something in the form of a summary of the methods has become almost imperative, and it is a significant fact that books on the synthetic use of metals have appeared almost simultaneously in both German and English.

The small volume by A. J. Hale includes all the more important methods, which, though not described exhaustively, are thoroughly typical and sufficiently elaborated to render the various processes easily understood. References are also given to the original literature, so that the reader may always supplement his knowledge by turning to the original source. The plan of collecting them at the end of the chapters involves a certain inconvenience, for it necessitates constantly turning over pages, and, as the authors' names are omitted, one is occasionally left in ignorance of rather interesting, if not indispensable, information. The proper place for a reference is surely on the same page as the subject referred to.

(3) The volume on organic chemistry by Dr. Hilditch is the third and last of the series of text-books on this subject which have been prepared for the use of technical institutes. It contains chapters on heterocyclic compounds, the purine group, polypeptides, carbohydrates, terpenes, and the alkaloids.

It would perhaps be more correct to call it a book of reference than a third-year text-book; for it is so closely packed with facts and formulæ that it would tax the powers of an exceptionally good memory to assimilate a fraction of the material in one year. It might also be added that the lettering of the formulæ, especially of the ring compounds, is a severe strain on the eyesight, and might be printed in larger type with great advantage. The book has, however, been carefully and thoughtfully compiled, and should prove useful not only to students of technical institutes

and university colleges, but to others who have an interest in the more intricate branches of organic chemistry.

(4) Among the more valuable of the series of monographs on inorganic and physical chemistry published under the editorship of Prof. Findlay is the volume on the viscosity of liquids, by Dunstan and Thole. The subject is, in a sense, in an elementary stage, but the foundations have been laid, and the results, which have been obtained by the authors who may be looked upon as pioneers in this branch of physical chemistry, promise a valuable aid in elucidating many interesting problems. As the authors state in the preface, the additive effect of a physical property is of little use for the purpose of studying structure; but viscosity, like optical rotatory power, is mainly constitutive, and the difficulty in both cases lies in the interpretation of the numerical values.

The various chapters describe the apparatus, methods of measurement and of calculation, the measurement of the viscosity of pure liquids, of mixed liquids, of electrolytic solutions, colloidal solutions; and the final chapters are devoted to discussing the relation of viscosity to chemical constitution.

It is impossible in the short space allotted to this review to discuss the results; but the volume is a unique contribution to chemical literature, and well worth reading.

(5) The monograph on intermetallic compounds, by Dr. C. H. Desch, has reference to those mixtures of metals which form true compounds, and the methods by which such compounds may be distinguished from simple alloys. That the subject is an intricate one may be judged from the numerous erroneous results which marked the first attempts in this direction, and bv the not altogether satisfactory character of the present available data. The first accurate investigations were made by Heycock and Neville in 1897 by means of the freezing-point curve, and these have been followed more recently by the work of Tammann and his pupils. That the subject has been very widely studied may be seen by the long list of references, more than 200 in number, which are given at the end of the volume. The chapters are divided into the following subjects: thermal analysis, microscopic structure, the isolation of intermetallic compounds, their physical properties and chemical nature. The subject is one of the first importance to metallurgists, to whom this excellent and complete summary should make a special appeal.

(6) "De la Pirotechnia," of Biringuccio, of which the present volume is a reprint, appeared in 1540, the year following the death of its author. It has been edited and annotated by A. Mieli, who has also added a valuable introductory and biographical notice. As the name of Vannoccio Biringuccio is little known to English students of chemical history, it may be stated that he was born at Siena in 1480 and died in 1539. His father was an architect, but the son devoted his attention chiefly to metallurgy and mining, and paid several visits to Germany and Austria and other countries in pursuit of his studies. In the disturbed state of Italy at this period, when the Italian towns were constantly in conflict, the fortunes of those who allied themselves with the ruling families were apt to suffer. It is not surprising to find that Biringuccio was twice banished from his native city, when his patrons, the Petrucci, got into hot water, and was also twice recalled.

He was a contemporary of George Bauer (Agricola), whose great work on mining and metallurgy, "De Re Metallica," appeared a little later; for in it a reference is made to Biringuccio, in which Agricola recognises the debt he owes to the work of his predecessor.

Mieli, in his introduction, comparing the work of Agricola with that of Biringuccio, says:

"In Agricola we have the mineralogist and metallurgist, and in certain respects the geologist. Agricola was a man of much erudition, and his work is full of classical references. But Biringuccio was something more. Not only do many portions of the book attest a profound knowledge of chemistry; but they reveal the artist, the craftsman, and the inventor. If Agricola has observed and described, Biringuccio has manufactured and invented new methods and machines, and shown his artistic temperament in the production alike of big and little things. He could cast a cannon as well as a church bell."

OUR BOOKSHELF.

Memorials of Henry Forbes Julian. Written and edited by his wife, Hester Julian. Pp. xix + 310. (London: C. Griffin and Co., Ltd., 1914.) Price 6*s*. net.

Henry Forbes Julian, sprung from a Scoto-Irish family, was born at Cork in 1861. During his childhood his family migrated to Bolton, in Lancashire, and there his taste for scientific research was aroused under the teaching of Sir Henry Roscoe at Owens College, Manchester. He began his life as a metallurgist and mining engineer in South Africa, where he did much exploring in the Barotse country, and visited the falls of the Zambezi. He devoted himself to developing the cyanide process of ore reduction, and in collaboration with Mr. E. Smart wrote a standard treatise, "Cyaniding Gold and Silver

Ores." In 1894 he carried out further research on behalf of the Frankfurt Gold und Silber Scheide-Anstalt, and as a consulting metallurgist made repeated voyages to Mexico and other parts of the American continent.

Mr. Julian was a man of wide scientific knowledge, a constant attendant at meetings of the British Association, and other scientific societies, and he had acquired a wide knowledge of literature. A modest, cheerful man, he made hosts of friends, and after his marriage to a daughter of William Pengelly, the well-known geologist and explorer of Kent's Cavern, his home at Torquay became the centre of much scientific and literary activity. On his last voyage to America, on work connected with a patent case, he perished in the wreck of the *Titanic*. Though few details of this final tragedy are available, he certainly displayed the heroism and unselfishness which were the leading characteristics of his life.

In the present memoir compiled by his widow the material is thin, and some of the less important incidents of his life are described with more detail than is necessary. But in the circumstances this is excusable, and the memoir gives a vivid sketch of a life devoted to the cause of science and of an amiable and attractive personality.

A Practical Handbook of the Tropical Diseases of Asia and Africa. By Dr. H. C. Lambart. Pp. xv+324+plates. (London: C. Griffin and Co., Ltd., 1914.) Price 8*s*. 6*d*. net.

We are told in the preface that "the intention of the author has been to show at a glance, by its alphabetical arrangement, the diagnosis and treatment of the principal tropical diseases; the subjects treated will be found stripped to essentials, and the pages nowhere encumbered with disputed points or theories still *sub judice*, the book thus being arranged for readiest reference."

Such works are seldom to be recommended, because they involve too brief and fragmentary a treatment of subjects which must be dealt with thoroughly if they are to be understood at all; and they are to be recommended still less in medical matters, which are concerned with the life or death of patients. Medical men in the tropics have enough time at their disposal to read at least much fuller text-books than this one, which is apparently designed for the most cursory of readers. Thus, the vastly important clinical theme of abscess of the liver, requiring the utmost care in diagnosis and in medical and surgical treatment, is dealt with in three pages (without mention of Rogers's emetin treatment); and the junior medical man who would trust to this brief note alone might go very seriously wrong.

The author, moreover, can scarcely be commended for the carefulness of his abstracts, or for his grammar, his drawings, or, indeed, his general design, and the accuracy of many of his statements is open to question. The whole work suggests a compilation taken down from previous text-books or from lecture-notes; and the number of similar books on the same subject is already too large.

Leitfaden für Aquarien- und Terrarien-Freunde. By Dr. E. Zernecke. 4, ganzlich neu bearbeitete Auflage von C. Heller und P. Ulmer. Pp. vii+456. (Leipzig: Quelle and Meyer, 1913.) Price 7 marks.

Dr. Zernecke's handbook for the amateur management of aquaria and the like is full of valuable information. It pays sufficient attention to amphibia, lizards, snakes, and such small deer, and it touches on the salt-water aquarium, but its full strength is concentrated on the popular fresh-water aquarium. Full directions are given for the installation, aeration, sanitation, and general maintenance of this humanising educational instrument, and a host of water-plants, fishes—both native and exotic—and invertebrates of all kinds are introduced with suitable credentials and attractive portraits.

The Continents and Their People: Africa, a Supplementary Geography By J. F. and A. H. Chamberlain. Pp. vii+210. (New York: The Macmillan Co. London: Macmillan and Co., Ltd., 1914.) Price 3*s*.

This book provides an account of Africa and its people which serves to supplement the more technical descriptions of the text-book. Opportunity is taken to give a full treatment of the industries dependent on dates and diamonds. The nomenclature of the States should have been brought up to date, and the account of the causes of the Nile flood should be revised.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Determination of Sex in the Gall-fly, "Neuroterus lenticularis" ("Spathegaster baccarum").

It is well-known that many Cynipid gall-flies of the genus Neuroterus (Spathegaster) have two generations in the year, one generation of parthenogenetic females and a second generation of males and sexual females. I have previously shown (Proc. Roy. Soc., B lxxxii., 1910, p. 88, and B lxxxiii., 1911, p. 476) that any individual parthenogenetic female has either only male or only female offspring, and that the eggs of the male-producers undergo maturation of a different type from those of the female-producers. I suggested that possibly the determination of male-producing or female-producing individuals depended on the existence of two kinds of spermatozoa. Further experiments extending over the last two years have shown that this suggestion is mistaken, and that the difference between the male-producing and female-producing parthenogenetic females is derived from the sexual female parent. It will take several months at least to complete the cytological investigation of the phenomena which I have in hand, and therefore it may be of interest shortly to record at once the results of the breeding experiments, for they show a type of sex-determination not previously known in the Hymenoptera.

The experiments indicate that any individual sexual female produces either only male-producing or only female-producing parthenogenetic offspring, but not both. Individual fertilised females were allowed to lay on sleeved oak-leaves in May, 1913; the galls produced by each were collected, and sleeved on oak leaves in March of this year. On examining the flies produced, I found that, with a few possible exceptions, the grandchildren of any one sexual female are either all males or all females. I have examined more than 9000 grandchildren of the twelve fertilised females sleeved in May, 1913, and among these there are about 2 per cent. of exceptions to the rule that all the grandchildren of any sexual female are of the same sex. The exceptions, however, do not occur in all the sleeves, but in rather less than half, and I have little doubt that they are due to wild flies having been able to lay eggs in the buds through the muslin of the sleeves. The wild flies were exceptionally abundant this spring, and it is difficult to prevent the buds from pressing against the muslin in such a way that a fly on the outside could not lay in them. I intend to test this possibility next spring, but meanwhile the results obtained make it certain that nearly, if not quite all, the grandchildren of any sexual female are of one sex, and that of the sexual females, those which have male or female grandchildren are about equally numerous.

Cambridge, September 21.

Asymmetric "Diffraction" and "Re-Diffraction" of X-Radiation.

Further work upon this subject, briefly described in previous letters (see Nature, July 16, p. 507), has shown that for any one position of the bulb and object the angle of diffraction is constant. This angle, however, varies with the distance of the object from the source in accordance with a simple inverse sine-law ($\sin\theta \times dcm = 7{\cdot}5$), over the wide range of 8° to 40°, and 50 to 10 cm. This and other well-marked differences from light have been already noticed in our previous papers, and a table of the sine values is given in the present (October) number of the *Röntgen Journal*.

A map of the hemisphere of X-rays, charted by the diffraction images of a lead disc, shows that there is an "optimum," or axis of symmetry, lying in the plane of the kathode rays and 30° from the normal to the anti-kathode (Fig. 3.). Around this axis the effects are increasingly asymmetric. This is shown by the variation of the white band (from a full circle to nearly a semi-circle) within the shadow, and of a dark area between it and the boundary of the image. The positions of maximum intensity have been determined by the photographic and electroscopic methods (see Nature, August 13, *Röntgen Journal*, July and October, 1914), and are found to be always directed to the optimum axis. The asymmetry has also been established with V-apertures and squares of metal, where the white band appears on one, two, or three (asymmetric), or four sides (symmetry) according to the relative positions (70° to 0°) to the axis of symmetry. The bulb must, of course, be rotated on the spot as centre. In addition to these effects, already described, we have now ascertained that the "diffracted" rays are almost entirely re-diffracted by a second edge. The re-diffraction (as in the case of primary diffraction probably) occurs in two directions, *i.e.* within and without the shadow. Moreover, these effects are again definitely asymmetric when other than optimum rays are used. For instance, a lead disc perforated by apertures symmetrically arranged is shielded by a solid disc of slightly larger dimensions to secure that no rays except those already diffracted by it can reach the second disc. The perforated disc may be placed 0·7 cm. from the plate, and 19 cm. from the anti-kathode, 2·7 cm. separating the discs.

Fig. 1.—Asymmetric. Extreme X-rays (Grazing anti-kathode) 70° from normal in plane at right angles to that of kathode rays.

Fig. 2.—Symmetric. Optimum X-rays 15° from true reflection and in plane of kathode rays, *i.e.*, 30° from normal to anti-kathode.

Fig. 3.—Map of hemisphere of X-rays (lead disc) showing radial structure of radiation. Reduced 4 diameters.

These rays, being normal to the disc, and leaving the anti-kathode at any other than the optimum angle, the images of the perforations will be seen (Figs. 1 and 2) to be increasingly displaced, distorted, and altogether absent in the extreme position. The asymmetry is marked at *opposite points*, and not at the ends of rectangular axes as would be the case were the phenomenon one of *ordinary* polarisation.

A black band *outside the shadow* is naturally only observed when the rays are thus shielded, for otherwise it falls in the area of undiffracted direct radiation.

In these experiments especial care has been taken to keep the milliamperage constant between 1 and 1·5, by means of a variable resistance in the primary.

I. G. Rankin.
W. F. D. Chambers.

90 Gordon Road, Ealing.

GLASS FOR OPTICAL PURPOSES.

THE importance of an adequate supply of optical glass of all the principal types cannot be overestimated. The improvement of the microscope has been and is still retarded for the want of suitable glasses, the construction of large telescopes is limited by the capacity of the glass-maker to supply suitable discs of glass, and the improvements made in the design of small telescopes cannot be extended to larger sizes for the want of suitable glass.

Photographic lenses, binoculars, range-finders, and telescopes of all kinds are dependent for their performance on the good quality, both optically and physically, of the glass used in them. The magnitude of this special branch of the glass-making industry may be gauged from the value of the German exports. In the last year for which figures are available the value of the exports of unworked optical glass exceeded fifty thousand pounds, and large quantities were exported as finished lenses. The characteristic of optical, as distinguished from other glass, is its great homogeneity; veins of material of different composition even in the form of very fine striæ render glass unsuitable for the better class of optical work.

The history of optical glass-making is to a large extent the history of optical progress. Dollond's discovery of the achromatic combination (1757) created a demand for flint glass suitable for optical purposes. At first this demand was met by the selection of the most suitable pieces from the glass manufactured for other purposes, but the demand for larger discs of flint glass led Guinand (1748–1824) to work out new methods of melting flint glass. The essential feature of his method was the continual stirring of the glass to prevent the formation of striæ of different density. Guinand migrated from Switzerland to Bavaria, and in conjunction, first with Utschneider and later with Fraunhofer, improved the process, so that larger blocks of good uniform glass could be manufactured regularly. On Guinand's return to Switzerland, Fraunhofer continued his experiments, and was able subsequently to make good discs of flint glass up to 10 in. in diameter. Meanwhile Guinand had increased the size of discs up to 14 in. diameter, and on his death in 1824 the secret passed to his sons, and through them to Bontemps in France. Bontemps' work was carried on by the French house of Feil, now Parra-Mantois, while Bontemps himself brought the secret process, in 1848, to the glass-works of Messrs. Chance.

For some time the principal advance was in the improvement of the physical properties of the glass, greater uniformity, greater transparency and more durability being aimed at. The calculation of the Petzval portrait lens and its successors led to a large demand for a glass intermediate in type between the ordinary flint and the crown. For this purpose, and for use in the other types of photographic lenses, the series of light flints was worked out. In this series the percentage of lead oxide increases as a higher refractive index is required.

The progress of the microscope makers required the extension of this series of glasses to denser flints, *i.e.* glasses of higher refractive index; at the same time small variations in the constitution of the crown glass were made to give slightly differing optical properties. In this way, by the year 1880 it was possible to make a complete series of glasses with their refractive indices ranging from 1·515 to 1·72. But these glasses had two special characteristics: as the refractive index increased, the dispersion, *i.e.* the difference in the refractive indices for light of two chosen colours, increased more rapidly, so that it was always necessary to use the glass of lower refractive index for the positive lens of an achromatic combination; also the dispersions of two glasses of different refractive index were not proportional throughout the spectrum, so that if a combination of a crown and a flint lens were made to bring the red light proceeding from an object to the same focus as the blue light, the yellow and violet light would not come to the same focus. The consequence was that all images appeared coloured, in spite of the choice of the most suitable curves for the two lenses; this defect is termed "secondary spectrum."

Many attempts had been made to obtain a pair of glasses which would enable the lens-maker to get rid of this secondary spectrum. The experiments of the Rev. W. V. Harcourt (1789–1871), which extended from 1834 to 1871, showed that this problem could be solved; he proved that the effect of substituting boric acid for part of the silica in the glass was to reduce the dispersion of the blue end of the spectrum, and so to make a flint glass which more nearly matched the ordinary crown glass. He was also able to modify the crown glass by using phosphoric acid, but wrongly attributed the result to the presence of titanic acid. Unfortunately these experiments did not lead to practical results, probably because of the expense attaching to experimental meltings on a practical scale.

The next stage in the development of optical glass was the investigation by Schott and Abbe (1881–1886) of the effects of using different materials. With consummate experimental skill, and assisted by generous grants from the Prussian Government, they were able to determine the effects of employing different materials. They were able to confirm Harcourt's results as to the action of boric acid, and correctly to attribute the effects observed by him to phosphoric acid. In addition, they were able to determine the effects of barium both with and without boric acid.

Now the use of boric acid in the ordinary lead glasses always leads to a glass which is more or less liable to spot, but by the use of barium instead of some of the lead this effect is reduced. The boric acid barium glass is, however, of special value, because in this case a high refractive index is associated with a low dispersion. It behaves as a crown glass as regards its dispersion, but

as a flint glass in respect of its refractive index. This property is of special value in the construction of modern anastigmat photographic lenses. These researches of Schott and Abbe were followed by the establishment of the Jena glassworks, where the new types of glass were made on a commercial scale.

The immediate results were—

(1) The manufacture of flint glasses containing boric acid; by the aid of these glasses it was possible to make three-lens objectives free from secondary spectrum, but these glasses are not so permanent as the older types.

(2) The series of phosphate glasses which proved chemically unstable and deteriorated in use.

(3) The boro-silicate crown glasses, which are of somewhat lower refractive index and dispersion than the ordinary crown glass. These are good glasses, and are now extensively used for small objectives and for the prisms used in prism binoculars.

(4) The dense barium crown glasses, containing barium and boric acid. These glasses are used in nearly all anastigmat photographic lenses, but they are difficult to make because such abnormal optical qualities are closely associated with chemical instability.

(5) The most important result was, however, the possibility of obtaining a large range of refractive index and dispersion, so that the designer was able to regard the dispersion and refractive index as more or less independent of each other.

He could design a photographic lens with little regard to the chromatic defects and correct this defect by proper choice of the dispersion of his glass.

These great successes led at first to a concentration of the optical glass industry in Jena, but the success of Chance in improving the quality of the older types of glass, and of Mantois in making the newer types, have somewhat modified this situation, though we are still dependent on Jena for some of the special glasses.

The manufacture of optical glass is not, however, to be lightly undertaken; there would be no great difficulty in finding the composition of glasses of the existing types, though it must be remembered that the mixture used will differ somewhat in composition from the final product. Great difficulties are associated with the purity of the materials and their proper mixing; the pots must be of clay, free from impurities which might colour the glass. The preparation of these pots requires skilled workmen of long experience, and the same may be said of the melting temperatures, the proper period of stirring, the rate of cooling, and the whole annealing process. At the same time, small variations of composition or treatment will affect the optical properties quite considerably. The experimental work associated with the production of special types of glass is expensive and troublesome, since the principal difficulties arise when we endeavour to change from the laboratory to the works scale, and at this stage a single failure may cost fifty pounds.

In view, however, of the importance to our industries and to the army and navy of an adequate supply of optical glass of various types, it is most desirable that our optical glass should be made in this country, and the manufacturers should be encouraged in every way to meet this demand. Success in this direction is, however, most likely to be achieved by scientific experimental work carried out in conjunction with those manufacturers who have already acquired valuable and essential experience in the manufacture of optical glass. S. D. CHALMERS.

THE BRITISH ASSOCIATION IN SOUTH AUSTRALIA.

ADELAIDE, AUGUST 12.

THE Australian meeting of the British Association opened in Adelaide on Saturday, August 8. The main party of overseas members arrived by the Orient mail steamer *Orvieto*, and numbered 150. It included the majority of the "advance party" to Western Australia. A smaller party of fifty members had arrived by the Blue Funnel steamer *Euripides* on the previous evening, and members arriving by other and earlier routes raised the total to approximately 290 overseas members. The local membership roll fell but a single unit short of 600 members, a figure significant of the keen interest taken by the people of South Australia in the advent of the Association.

The Adelaide meeting has been favoured with perfect weather, and only the outbreak of the war cast its gloom over a meeting which otherwise fell nothing short of complete success.

On the afternoon of arrival a special congregation was held by the University of Adelaide, when the following honorary degrees were conferred:—*D.Sc.*—Prof. W. J. Sollas, Prof. A. Penck, Prof. T. W. Edgeworth David, Prof E. W. Brown, Sir Oliver Lodge, Prof. H. Jungersen, Prof. G. W. O. Howe, Dr. C. F. Juritz, and Prof. von Luschan. *M.D.*—Prof. G. Elliot Smith. *M.A.*—Mr. A. D. Hall, Prof. A. P. Coleman. *B.A.*—Sir Charles P. Lucas. *B.Sc.*—Prof. T. Hudson Beare.

In the same evening a reception was given to the overseas members by the State Government, when the visitors were welcomed by his Excellency Sir Henry Galway, Governor of South Australia, and by Mr. Peake, its Premier.

Owing to the short space allotted to the Adelaide Session, sectional meetings were not included in its programme. Presidential addresses were, however, delivered in geography by Sir Charles Lucas and in agriculture by Mr. A. D. Hall.

Two evening discourses were also given in the Adelaide Town Hall by Sir Oliver Lodge, on "The Ether of Space," and by Prof. J. W. Sollas on "Ancient Hunters." Both were listened to with keen appreciation by a large audience.

The major part of the Adelaide programme was occupied by excursions, which were well patronised by the visiting members. On the day of arrival a party of fourteen left Adelaide for an excursion to Broken Hill and the smelting works at Port Pirie. On Monday morning about fifteen members departed, under the leadership of Mr. Walter Howchin, to visit places of geological interest to the south of Adelaide, chief among their objects of investigations being the remarkable evidences of glaciation discovered by Mr. Howchin. On the same day a botanical excursion to the hills in the vicinity of Adelaide, under the leadership of Prof. T. G. B. Osborn, and an anthropological excusion to Milang on the shores of Lake Alexandrina to inspect a party of aborigines there, was made under the guidance of the veteran ethnologist, Prof. E. C. Stirling, who is also the chairman of the local reception committee.

On Tuesday, August 11, a second botanical excursion by motor-car to Mannum on the Murray was made by about a dozen members, and an excursion to Roseworthy Agricultural College by about twenty-five more. Members who did not participate in other excursions were conveyed on Monday by special train to Angaston, a small town fifty-one miles from Adelaide and the centre of a very important viticultural industry, where they were entertained at luncheon by Mr. Charles Angas.

On Tuesday a large number of members were entertained to luncheon by the Adelaide branch of the Commonwealth Club. On Wednesday afternoon, August 12, overseas members departed in three special trains for Melbourne.

DR. H. J. JOHNSTON-LAVIS.

HENRY JAMES LAVIS, who was descended from a Huguenot family settled in Devonshire, and added his mother's name to his own, was born on July 19, 1856, and was unfortunately killed in a motor accident near Bourges, department of Cher, on September 10. After receiving his early education in a private school, Johnston-Lavis commenced his medical education at University College, London, and here came under the influence of Prof. John Morris, from whose teaching he acquired a passion for geological studies. Joining the Geological Society when only nineteen years of age, he had written several geological papers, one of them published in the Journal of the Geological Society, before he was twenty-one. After obtaining his degree of M.R.C.S. in London and holding some minor medical posts in this country, he proceeded in 1880 to Naples, where he established himself as a consulting physician, taking the degree of M.D. in the University of Naples in 1884, and acting as medical officer to Sir William Armstrong's works at Puzzuoli from 1892 to 1897.

It was at Naples that Johnston-Lavis found his most useful sphere of geological labour; besides keeping a diary with photographic records of the action of Vesuvius, he prepared a valuable geological map illustrating the past history of the volcano, with petrological studies of its ejected materials. Incidentally, these studies led to one of his most important memoirs, undertaken in conjunction with Prof. J. W. Gregory, in which the non-organic origin of the one-time famous *Eozoōn canadense* was finally demonstrated.

In addition to his studies of Vesuvius, Johnston-Lavis did much useful work in connection with the vulcanology and seismology of the whole South Italian region. Between the years 1892 and 1897 Johnston-Lavis was in the habit of spending his summers at Harrogate, where he acted as a consulting physician. In 1895 he left Naples and, having taken a degree of M.D. at Lyons, established a practice on the Riviera at Beaulieu, while in 1909 he added to this a summer practice at Vittel in the Vosges. His scientific energies never flagged, and more than 160 papers—on volcanoes, earthquakes, mineral waters, and medical subjects—were issued by him, some of them dealing with important theoretical questions. Many geologists and others who visited the Mediterranean area were indebted to Johnston-Lavis for the friendly and valuable aid which he was always ready to afford.

NOTES.

THE death is announced, at seventy-five years of age, of Dr. A. S. Bickmore, formerly curator of the American Museum of Natural History, New York.

IN consequence of the closure of the Anglo-American Exhibition, the visit of the Geologists' Association to the science section, arranged for October 10, will not take place.

DR. HENRY OWEN, treasurer of the National Library of Wales, has been appointed a member of the Royal Commission on Ancient Monuments in Wales, in succession to the late Sir Edward Anwyl.

THE death is announced, by accidental drowning, of Dr. L. C. P. Ritchie, late president and secretary of the Royal Medical Society of Edinburgh, and the author of a number of papers on medical subjects.

ANNOUNCEMENT was made in NATURE of August 20 that, in consequence of the war the publication of the "British Pharmacopœia" had been postponed. The General Medical Council has resolved that advance copies should be made accessible to the public for inspection at the offices of the council in London, Edinburgh, and Dublin on October 1, at 10 a.m., and thereafter from 10 a.m. to 4 p.m. daily. The work will be published at the end of the year.

THE council of the Junior Institution of Engineers has elected the Marquess of Graham as president of the institution for the year 1914–15, in succession to Sir Boverton Redwood, Bart. The Vickers prize, consisting of a gold medal and premium of instruments or books, has been awarded to Mr. James Richardson, for his paper on high-power Diesel engines: their

development for marine service. Mr. Richardson has also been awarded the institution medal for the same paper.

THE Board of Trade has arranged for a Commission consisting of representatives of the Board of Trade, the Timber Trade Federation of the United Kingdom, and the Mining Association of Great Britain, to proceed to Canada and Newfoundland in order to inquire into the possibility of opening up new sources of supplies of mining timber for use in the coal mines of Great Britain. Inquiries on the subject should be addressed to Mr. C. F. Rey, Board of Trade, Queen Anne's Chambers, Westminster.

THE death is reported of Dr. W. L. Dudley, a prominent American chemist. He was born in Kentucky in 1859, and was professor of chemistry and toxicology at Miami Medical College, Ohio, from 1880 to 1886. In the latter year he was appointed to the chair of chemistry in Vanderbilt University, where in 1895 he became dean of the medical department also. He was secretary to the inorganic chemistry section of the St. Louis Congress in 1904, and U.S. Commissioner to the London Congress of Applied Chemistry in 1909. Dr. Dudley had devised an important process for working and electroplating with iridium.

THE war is likely to lead to some readjustment of the trade of the world. The Decimal Association points out in a letter we have received that if British manufacturers are to secure any of the trade which Germany has hitherto carried on with neutral countries, they must be prepared to adopt metric measures of weight, and so on. The association will be glad to help manufacturers and merchants who need assistance, and, if there is a demand, to arrange lectures under the auspices of chambers of commerce during the coming winter. Communications should be addressed to the secretary of the association at Finsbury Court, Finsbury Pavement, London, E.C.

THE death occurred, on September 20, of Mr. William Ascroft, of Cheyne Walk, Chelsea, in his eighty-second year. Mr. Ascroft was responsible for the six beautiful crayon sketches of twilight effects published by the Royal Society in the report on the eruption of Krakatoa in August, 1883. In the November following, the extraordinary twilight glows in the British Isles commanded general attention, and their probable connection with the Krakatoa outburst was pointed out. Mr. Ascroft made his drawings on the bank of the Thames, a little west of London, on the evening of November 26, 1883. They represented the grand general colouring of the western sky from shortly after sunset (3h. 57m. p.m.) to the final dying out of the afterglow at about 5.15 p.m.

IN the September issue of *Man,* Mr. W. N. Beaver discusses the eating of human flesh in the western division of Papua. A long experience of almost every district of British Papua inclines him to believe that while ritual or ceremonial does in many cases form the prime reason for cannibalism, in by far the greater number of cases human flesh is eaten because it is a food and is liked. The practice, however, is not habitual, but sporadic. It is said that snake-eaters are always cannibals. This is not a certain fact in Papua, but it is certainly a coincidence that the majority of snake-eating tribes in the island are also cannibal.

IN *Man* for September Mr. J. P. Johnson describes a collection of pygmy implements from Western Australia in the Perth Museum, and others from Eastern Australia in the Sydney Museum. Like those from South Africa, he regards them as merely diminutive forms or varieties of what French archæologists term the Audi, Chatelperron, and Gravette *pointes* or *couteaux.* These are characteristic of the Aurignaco-Magdalenien specimens of north-western Europe where the crescent is absent, and are prominent in the Capsian specimen of Sicily where the crescent is present. In Australia, however, they do not appear to be associated with scrapers as in Europe and South Africa.

ABOUT 1830 some Chinese and Malay convicts confined in the jail at Mahableshwar, the chief hill station of the Bombay Presidency, are supposed to have introduced the cultivation of the strawberry, which has now become a flourishing industry. The attempt to introduce plants from Saharanpur failed, and the present stock was obtained from Bangalore, where its previous history is unknown. Though they are good and command a ready sale, the berries are capable of much improvement. Dr. W. Burns, economic botanist to the Government of Bombay, who gives a valuable account of the industry in vol. ix., part iii., of the official Agricultural Journal of India, believes that if new stock can be introduced from Europe and America, there is hope of the production of high-class fruit in large quantities in the Yenna Valley.

IT is satisfactory to observe that many field clubs and local natural history societies are devoting attention to the preparation of a flora of the districts in which they operate. The Leicester Literary and Philosophical Society, in its Transactions, vol. xviii., for 1914, recently published, describes the work that is being carried on by their initiative. Many important discoveries, such as *Ceratophyllum submersum, Rumex pulcher,* besides cryptogams, have been made. Negotiations with the Uppingham and Rutland Natural History Societies have resulted in an arrangement to include Rutland in the Leicestershire work. So far as the original survey on ecological lines is concerned, the general editor has now defined the main lines of vegetation, and has recorded them on the 6-in. maps. An appeal for assistance from local workers has met with active support.

IN the notice of the recovery of the type specimen of *Pliolophus vulpiceps* in our issue of September 17 it should have been stated that Messrs. Flower and Garson (Cat. Osteol. Mus., R. Coll. Surgeons, part ii., p. 380, 1884) were the first to suggest the identity of Pliolophus with Hyracotherium.

ACCORDING to an article contributed to a Maltese journal of July 23 by Mr. G. Despott, of the Natural History Museum, Malta, the cetacean alluded to in

Nature of August 13 (p. 620) as having been stranded at Birzebbugia on July 20, is undoubtedly, as suggested in that note, a blackfish (*Globicephala melaena*). The identification is confirmed by photographs forwarded by Mr. Despott, who states that this specimen is the first record of the species in the Mediterranean.

From the report for 1913, contained in vol. iv., No. 8, of its journal, we learn that the East Africa and Uganda Natural History Society continues to maintain its record of progress and prosperity, the number of new members being greater than in any previous year. His Excellency Sir H. C. Belfield has been pleased to collect a fund which is to go towards the establishment of a permanent museum, with a curator, and a plot of ground in a central position in Nairobi has been reserved as a site for the proposed new buildings. A feature of the aforesaid number of the society's journal is a coloured plate of the African brown-bellied kingfisher (*Halcyon semicoeruleus*), illustrating an article on this strikingly coloured species by Dr. V. G. L. van Someren.

In concluding his article on pattern-development in mammals and birds in the September issue of the *American Naturalist*, Dr. G. M. Allen discusses partial albinism in wild birds, and what is termed "centrifugal coloration" in both groups. In the former section it is suggested that the white eyebrow-stripe in the so-called ringed guillemot—now known to be a special phase of the ordinary *Uria troile*—represents an incipient albinism forming a line of demarcation between the dark ear-patches and crown-patches. The author would expect to find this white in young birds, and suggests that, if of a recessive nature, it may eventually be developed in a much larger number of members of the species than is at present the case. As regards centrifugal coloration, this is the development of black pigment at the extremities or points of the body, as exemplified by the black nose and tail-tip not infrequently seen in domesticated cats. The so-called Himalayan rabbits, in which the whole animal is white, with the exception of the black nose, ear-tips, and toes, form another striking example. The paper winds up with a summary of the author's views.

In connection with the military operations of our Japanese allies in the province of Shantung, the meteorological observations made in Korea, on the opposite shores of the Yellow Sea, for about ten years, are of especial interest. We have recently received the results for the year 1912, and for the lustrum 1906–10. The following extracts from these valuable data, refer to stations in the north-west and south-west of Korea for the lustrum in question. *Chemulpo*: Highest mean monthly maximum temperature (August), 82·8°; lowest mean monthly minimum (February), 19·6°; annual rainfall, 31 in., on ninety-seven days; sunshine, 2726 hours (61 per cent. of possible amount). *Mokpo*: Temperature as above, 86·4° (August); 27·9° (February); rainfall, 38·3 in., on 126 days; approximate sunshine, 2310 hours (52 per cent. of possible amount). The instruments and method of observation are of the same excellent character as those at meteorological stations in Japan, and the tables are carefully prepared by Mr. Y. Wada, director of the observatory at Chemulpo.

We are glad to see from *Symons's Meteorological Magazine* for September that Dr. Mill is able to resume the editorship after an interval of nearly a year. The size of the magazine has had to be somewhat reduced, owing to the fall in the income of the British Rainfall Organisation through the war. This number contains an interesting article by Mr. H. H. Clayton and Mr. W. M. Hays, entitled "Arguments for Basal and Immediate Crop Estimates," the gist of which is the possibility of substituting for present estimates of crop conditions, based on reports by growers and bureau agents, opinions based on climatic records supplied by a World Meteorological Organisation from daily weather telegrams. The publication by the U.S. Weather Bureau of daily weather charts for the northern hemisphere, and the collection and publication of data from stations to represent the meteorology of the globe, by the efforts of the Solar Commission of the International Meteorological Committee and of the Meteorological Office, are great steps in the above direction. But, as we have before had occasion to point out, the proposals made to the meteorological conferences and meetings to promote the establishment of an international weather bureau have not met with any definite encouragement.

In the Bulletin of the American Mathematical Society, vol. xx., p. 10 (July), Prof. Edward Kasner discusses certain exceptions to the general rule according to which the ratio of the arc to the chord of a curve tends to the limit unity. In the case of an ordinary singular point the ratio may, of course, be indeterminate, but the author finds that in the case of certain imaginary curves the ratio may have a definite limit different from unity at some particular point or points, even if the curve be analytic in the neighbourhood of the point or points in question. The most typical case is that of a plane curve at a point where the tangent passes through one of the imaginary circular points at infinity. At such a point the ratio of chord to arc becomes $\frac{2}{3}\sqrt{2}$, $\frac{2}{4}\sqrt{3}$, $\frac{2}{5}\sqrt{4}$, and so on according to the order of contact with this particular tangent. The discrepancies are due to the fact that the elements of chord and arc from the point to a neighbouring point both vanish to the first order of small quantities.

In the Proceedings of the Physical Society for August (vol. xxvi., part 5) Dr. Lees discusses the connection betwen Fourier's series and the method of least squares. This connection was pointed out in Tait's "Natural Philosophy" without proof, and we believe that several other writers have dealt with the question in greater or lesser detail, possibly covering the same ground. The present paper contains a brief proof of the proposition that if it is required to obtain a finite trigonometric series having given values for a corresponding finite number of values of the argument, the series obtained by the Fourier expansion makes the sum of the squares of the errors a minimum.

It was in 1871 that Lord Rayleigh first proposed a theory to account for the scattering of light by small particles, and in particular to explain the blue sky. Various other papers have followed on the subject by different writers. In the *Bulletin de l'Académie des Sciences de Cracovie,* Dr. Ladislas Natanson, in a paper communicated last January, discusses the problem on lines consistent with the modern electron theories. The author first considers the effect of a vibrating electron in the presence of a train of electromagnetic waves, using Planck's formula. An expression is found for the energy of the scattered wave; this is found to vanish in the direction of propagation and to be a maximum in the equatorial plane. The electric and magnetic energies are not in general equal. When it is sought to deal with a medium containing a large number of such vibrators the problem cannot be solved without making certain assumptions which can only be regarded as a first approximation. With these the author obtains formulæ for the coefficient of transmission of the medium and its dependence on the wave-length.

The scientific study of the acoustical properties of public buildings is a subject the neglect of which may involve losses of thousands of pounds. The large hall presented to the University College of North Wales by Sir John Prichard-Jones possesses an echo quite equalling the famous one of the baptistery at Pisa, but this feature renders it useless for many purposes for which it would otherwise be in requisition. Mr. F. R. Watson's article on the acoustics of auditoriums in the University of Illinois Bulletin xi., 29 (Bulletin No. 7, Engineering Experiment Station; London: Chapman and Hall, 1914, price 20 cents) is a welcome contribution to this study. The investigation refers primarily to the auditorium of the Illinois University, which has formed the subject of the author's researches since 1908, one year having been spent by him in general study abroad. Mr. Watson discusses Sabine's formulæ for the effect of absorption on reverberation, and arrives at the following general inferences:—Wires have but little effect; air currents due to ventilation may even be worse than useless. In his survey of the building in question he has determined both experimentally and theoretically the paths of the sound waves reflected from the various surfaces, plane and curved, of the building, and the formation of foci; and a remedy has been proposed involving the placing of curtains in positions determined from these observations. The sources of sound employed in these experiments include a ticking watch, an alternating arc current in presence of a concave mirror, and a directed source ingeniously obtained with the aid of a metronome. But the Illinois auditorium with its concave walls and curved roofs is so different from the rectangular Prichard-Jones Hall at Bangor, that an investigation which is sufficient for one building will scarcely be likely to explain, except very partially, the defects of the other.

It is remarkable that no extended use has ever been made of a phonographic attachment to a telephone for recording spoken messages. The Poulsen telegraphone in which the received currents produced a record by magnetising a steel wire or tape was undoubtedly a scientific success, and perfect speech reproduction could be obtained by its means, but it never made a position for itself as a commercial instrument. The reason for this may have been that the telegraphone had to be electrically connected to the line, and there were possibly some technical or administrative objections to such an addition to a subscriber's instrument. From an article in the *Scientific American* it appears that a new Edison instrument, called the "telescribe," has recently been evolved in which the arrangements are more akin to the Edison wax phonograph. The ordinary telephone receiver of the subscriber's instrument is placed against a very sensitive transmitter, in a local circuit with a battery and another "special" telephone receiver, and the latter is arranged to emit its sound waves against the ordinary sound-recording diaphragm of a phonograph. The instruments of this local circuit must apparently be designed so as to act as a telephone relay and increase the amplitude of the vibrations sufficiently to cut the wax phonograph cylinder. A second receiver on the subscriber's set enables him to listen to the message, and even to contribute his share of the conversation, so that the whole or part of it may be recorded as he desires. This is certainly an ideal arrangement if it gives satisfactory records without impairing the clearness of the articulation by the relaying process.

The value of the scientific exploration of the agricultural products of India is well illustrated in a paper by Mr. C. Somers Taylor, agricultural chemist to the Government of the province of Behar and Orissa, contributed to vol. ix., part iii., of the official Agricultural Journal of India. Discussing the problem of the varying amount of sugar obtainable from cane juice, he remarks that at one time this was thought to be dependent on the presence of glucose. This theory has now been proved to be unsound by the great Dutch sugar chemist, Geerligs. On the other hand, the same authority—and his conclusions are verified by Indian research—shows that a high percentage of potash is, as a rule, accompanied by a low quotient of purity, a low saccharine content, and a high glucose content when the cane is ripe. The question of potash content is carefully examined by Mr. Somers Taylor in this paper, and he concludes that work on the potash content of cane juice is likely to be of great value in the examination of different varieties of canes, and in consequence the official chemists propose to take up this study more fully in the near future.

The Institute of Chemistry has issued a "History of the Institute, 1877–1914," compiled, by direction of the council, by Mr. Richard B. Pilcher, the registrar and secretary. The institute had its origin in a meeting held on April 27, 1876, to discuss the necessity for organisation among chemists for the purpose of enhancing their professional status; at this meeting Prof. (later Sir) Frederick Abel presided. A committee was appointed to confer with the Chemical Society with regard to a scheme for establishing an organisation of professional chemists, and ultimately

it was decided to form a new association, and the first officers of the council, with Prof. Frankland as president, were elected in 1877. The membership, which in February, 1878, was 225, had grown in March, 1914, to 1454. Recently new buildings have been erected, duly equipped, and suitable for the purposes of the institute, at a cost of 17,080*l*. Owing to the dispute in the building trades in the early part of this year, these new buildings have not been completed, so that the institute will occupy their present premises at 30 Bloomsbury Square, if necessary until Christmas. A special council meeting was held on June 12 to consider the question of bringing the work of the institute more prominently before the public. Four lectures will be given during the winter months.

OUR ASTRONOMICAL COLUMN.

COMET 1913*f* (DELAVAN).—Delavan's comet is becoming a less favourable object for evening observation owing to the diminution of its declination and its movement westward among the stars. It attains, however, a considerable altitude in the hours just before dawn, and this is the best time for observation. It is situated not far from the star χ Ursæ Majoris, and is approaching α Can. Venaticorum. On clear evenings it is a conspicuous object near the northern horizon and its tail has increased considerably in length. The series of fine nights recently experienced has given opportunities for a considerable amount of observation.

THE RECENT SOLAR ECLIPSE.—The recent eclipse was observed at Paris and Algiers, though at both stations it was only partial. At the Observatory of Paris MM. Bigourdan, Boquet, Chatelu, and Le Morvan made the observations, while M. Gounessiat worked under good conditions at Algiers. The results of these observations have been communicated to the *Comptes rendus*, August 24 and 31. In the case of Paris, M. Bigourdan determined the observed minus calculated times of commencement and end as −23 sec. and −38 sec. respectively. M. Gounessiat, from his observations at Algiers, gives the corrections to his observed times of first and last contact as −25 sec. and −38 sec. respectively.

FRENCH PROVINCIAL OBSERVATORIES IN 1913.—The pamphlet published by the French Minister of Public Instruction and Fine Arts, entitled "Enquêtes et Documents relatifs à d'enseignement supérieur," vol. cix., contains the reports of the French provincial observatories for the year 1913. The observatories dealt with are Algiers, Besançon, Bordeaux, Lyons, Marseilles, Nice, Pic du Midi, and Toulouse. The volume gives a good idea of the various branches of astronomical and meteorological work, which forms the main routine work of the several institutions, besides stating the actual progress made during the past year. It gives further lists of the various staffs, showing that each observatory employs from six to nine scientific members, excluding the Pic du Midi, which is composed of four.

STRONG MAGNETIC FIELDS FOR SOLAR RESEARCH.—MM. Deslandres and Perot present, in the *Comptes rendus* for August 24 (vol clix., No. 8), the second of their series of experiments for the production of most intense magnetic fields. This work is particularly important in its bearing on experiments relative to researches on solar magnetic fields. It is pointed out that the progress of advance in the construction of electromagnets is to be found, not in the saturation of large masses of iron, but in the judicious use of intense electric currents. The authors of the above paper do not therefore advocate the exceedingly ponderous apparatus of Weiss, which weighs about 100 tons, but are directing their attention to comparatively small and light electromagnets. In the present paper they describe somewhat in detail the methods they adopt and the success already achieved speaks well for further advance. With the support of the Princess of Polignac, the electric supply company of Paris, and the electric station of the Bon Marché, they have been able to test their new method of water cooling of the magnetising coils, and have without the use of iron reached a field of 50,000 gauss as measured by its effect on one of the zinc lines. They use thin silver tape instead of wire in their coils, and cool it by a stream of water flowing across instead of along the tape. The difference of potential between two consecutive turns of the tape is kept below 1·4 volts in order to minimise electrolysis. By the use of iron cores the authors hope to be able eventually to reach fields of 150,000 gauss, but their work has been interrupted by the war.

RECENT ECONOMIC ZOOLOGY.

THE University of California has recently issued (Publications in Zoology, vol. xi., No. 14, 1914) a monumental paper on economic ornithology by Mr. H. C. Bryant; although a single species only —the Western Meadow-lark (*Sturnella neglecta*)—is dealt with, the memoir extends to 133 pages, with four plates and many statistical tables. All modes of investigation—field work, experiments with captive birds, examination of stomach contents of adults throughout the year and of nestlings, summaries of the influence of season, locality, age and sex, on the nature of the food—have been brought to bear on the problem. The farmers of California, in reply to circulars sent out by the author, were about equally divided in opinion as to whether this particular bird is harmful or not. Mr. Bryant comes to the conclusion that except for a reprehensible habit of destroying sprouting grain in spring, the Western Meadow-lark must be regarded as beneficial from the numbers of harmful insects and weed-seeds that it devours. In addition to the economic interest of this paper, a discussion of the value of "protective" adaptations in insects appeals to the naturalist. A large proportion of the stomachs examined contained hairy caterpillars, ants, wasps, and bees, as well as "cryptically" coloured grasshoppers and weevils. The author admits, however, that the factors of situation and motion at the time of capture might explain why the form and hue of these latter failed to protect them.

The last published part of the Bulletin of Entomological Research (vol. v., part 1, April, 1914) contains an interesting account of the Gold Coast by Dr. J. J. Simpson, who has paid special attention to tsetse-flies and other blood-sucking insects. Mr. W. W. Froggatt has a short but valuable note on sheep-maggot flies in Australia, where species of bluebottle (Calliphora) have, during the last ten years, acquired the habit of "blowing" healthy sheep, as the greenbottle, *Lucilia sericata*, has long done in this country. A minute chalcid parasite does something to keep the flies in check, but they are said to have caused the loss of a million pounds to stockowners last year in New South Wales alone. *Glossina morsitans* in Nyasaland is discussed by Dr. J. O. Shircore, who has traced the fly to four "primary centres," where extermination might be attempted with some chance of success.

Besides the bulletin, the *Review of Applied Entomology* continues to be issued by our Imperial Bureau. The summaries of papers from all parts of the world are of great value to workers, who will doubtless be especially grateful to have the essence of much important Russian literature—otherwise unavailable—brought within their reach.

The twenty-first report of the Danish Biological Station to the Board of Agriculture (Copenhagen, 1914) consists of an important memoir by Dr. C. J. G. Petersen on the animal communities of the sea-bottom and their importance for marine zoogeography. By means of a new "bottom-sampler" the whole animal population of a square metre of the area under investigation can be brought up in one haul, and the results of numerous "valuations" of the sea-bottom at two hundred stations in the North Sea and the Skagerrak are set forth in statistical tables and photographs. the latter reduced to scale, giving a vivid impression of the density of the population and the relative abundance of its various members. By this method of research, Dr. Petersen treats the marine fauna as botanists of the ecological school treat the vegetation of an area, and defines an "Echinocardium-Venus" or a "Brissopsis-Turritella" community as characteristic of certain regions. In the use of this method the author believes that "the animals which are not seasonal and which compose an important part of the whole mass of the community owing to number or weight, will presumably be best suited for characterising the community, and must also be considered as giving a good idea of the outer conditions on which the community is dependent." G. H. C.

FATIGUE STRESSES.

SINCE Wöhler published in 1871 the results of his tests on the behaviour of steel under repeated stresses a great deal of work has been done in this direction. The experiments of Stanton, Eden, Rose, and Cunningham are well known in this country. The subject is a difficult one, and is complicated by the lack of any satisfactory correlation between the tests. Further, experiments on repeated and alternating stresses take a long time to carry out.

In his memorandum to the Manchester Steam Users' Association, Mr. C. E. Stromeyer gives account of some interesting experiments. Mr. Stromeyer has found that all his tests could be harmonised by arranging for successive fatigue fractures on the same test piece, 1 in. or $1\frac{1}{2}$ in. apart. From these tests an empirical relationship was derived, and found to be applicable not only to bending fatigue tests, but also to push-and-pull, and to torsion fatigue tests. The empirical formula is $N=10^6C^4 \div (S_n - Fl)^4$, in which $\pm S_n$ is the nominal fatigue stresses to which a sample is subjected, Fl is the fatigue limit of the material, C is a constant for the given material, and N is the number of repetitions of the stress S_n, which the material will stand before it fractures. The close agreement of this formula with the test results is demonstrated by diagrams given in the memorandum.

An idea for determining the fatigue properties by means of a single test suggested itself, and proved to be so practical that a new machine has now been constructed for the association with which fatigue tests on the improved lines will shortly be undertaken, both as regards push-and-pull stresses, bending stresses, and torsion or shearing stresses. In principle, the new test consists in determining the stress at which the temperature of the test piece begins to rise in consequence of internal friction. There is practically no internal friction in steel up to a certain limit of stress, and hence no heat would be developed in an alternating or repeated stress test within this limit of stress. The test piece was surrounded with a loose sleeve of thick india-rubber, and circulating water passed along the annular space between the test piece and the rubber; delicate thermometers were used to measure the difference in temperature of the inlet and outlet circulating water. At low stresses no difference in temperature was noticed; when a difference of about 0·01° C. was noticed the fatigue limit was supposed to have been reached, but the fatigue stresses were increased slightly in order to confirm this indication. A considerable difference in temperature was now apparent, but would generally disappear again if the alternating stresses were reduced below the limit. These calorimetrically determined fatigue limits were generally defined very clearly, and may be depended upon as being nearly correct.

Further, the calorimetric fatigue limits agree remarkably well with the fatigue limits Fl found by extrapolation of series of tests carried to the point of fracture. Hence it is possible to shorten fatigue testing from several weeks' or months' duration to one or two hours. A single test piece is prepared—duplicates, of course, are desirable—and submitted to gradually increased fatigue stresses until the fatigue limit Fl is found calorimetrically; then the stresses are increased until a large quantity of heat is evolved, and the alternations of stress are counted up to fracture. These tests fix both Fl and also the coefficient C.

The method seems very promising, and may lead to a simple workshop fatigue test of considerable practical value being adopted in many works where the time occupied in alternating stress tests has hitherto been a barrier.

THE ROYAL SOCIETY OF NAPLES.[1]

THE *Atti* and *Rendiconti* of the Royal Society of Naples for the past year show what valuable work is being done by this Society. The *Atti* (corresponding to our Transactions) contain sixteen memoirs, occupying more than five hundred quarto pages. Papers of less importance are inserted in the *Rendiconti*, which correspond to our Proceedings. Attention should be directed to the very useful and extensive bibliographies which accompany several of the memoirs.

While all the principal sciences are represented, it is to the domain of pure mathematics that the more important work belongs. Mr. G. Gallucci contributes a valuable memoir on configurations (*Atti*, No. 4); Mr. D. Montesano, others on the Cremonian groups of numbers and the bilinear complexes of conics in space (Nos. 7 and 8); Prof. E. Pascal describes integraphs for differential equations (No. 16), and for the graphical solution of integral equations; Mr. G. Andreoli explains a method of determining superior limits to the moduli of the complex roots of a given algebraic equation. In the *Atti* (No. 10) Mr. R. Giacomelli gives a biographical notice of Giuseppe Ballo, a contemporary of Galileo. Among other papers may be mentioned those of E. Guerrieri on the light-curve of Mira Ceti, drawn from numerous observations made during the years 1902–13, of Dr. M. Fidele on the innervation of the reptilian and batrachian heart (*Atti*, No. 2), and of F. Zambonini on Vesuvian mineralogy (No. 12).

The condition of Vesuvius since the eruption of 1906 is the subject of several interesting papers. Prof. G. Mercalli, whose death last March deprived

[1] "Atti della Reale Accademia delle Scienze Fisiche e Matematiche (Società Reale di Napoli)," vol. xv, 1914; Rendiconto, vols. xix, xx, June, 1913—June, 1914.

us of an unwearied investigator of Vesuvian phenomena, contributed two notes in July, 1913, on recent changes in the crater which, in his opinion, point to an early revival of activity after seven years' rest. Mr. O. De Fiore, in a memoir on the period of repose in Vesuvius which began in 1906 (*Atti*, No. 14), remarks that the great outbursts attract most attention, but urges that the intervening periods of repose are also deserving of study, for it is through their investigation that we may be led to foresee a coming revival of activity. He distinguishes three principal, though overlapping, phases in the Vesuvian period of repose, to the first of which—the degradation of recent forms—the present memoir is devoted. Lastly Dr. A. Malladra, of the Vesuvian observatory, describes the solfatara of the Atrio del Cavallo, which separates the modern cone of the volcano from the cliffs of Monte Somma.

THE AUSTRALIAN MEETING OF THE BRITISH ASSOCIATION.

SECTION L.

EDUCATIONAL SCIENCE.

Opening Address by Prof. John Perry, D.Sc., LL.D., F.R.S., President of the Section.

I wish to make some general remarks upon the science of education. As in the chapter which was entitled "The Snakes of Iceland," and which merely consisted of the sentence, "There are no snakes in Iceland," I might finish this Address at once by saying "There is no science of education." There is the art or practice of teaching or pedagogy, just as there used to be the art of engineering. It was only slowly that the subject of Section G, the Science of Engineering, was created; but the subject of Section L, this section, has still to be created. In the creation of a science we first and for long periods have the observation of detached phenomena and disputes about them, because the phenomena seem complex, having no obvious connection with one another; then experiments simplify things, and gradually the science is created by inductive reasoning and research. In education, observation and disputes have occupied much time, and we cannot say that the phenomena have become much simplified by such experiments as have been made. Every man in the street considers that his opinions on education are as good as those of anybody else. I suppose that almost nobody would refuse to make an after-dinner speech on any kind of education, whereas he would not dream of speaking about geometry, or chemistry, or physics, or physiology unless he had studied these subjects. Any ordinary citizen thinks himself fit to be a member of the governing body of a school or college, and the disasters due to this belief are worse than what would occur if we gave to such men the command of ships. The ordinary man, especially the Parliamentary man, who thinks that the members of a committee on some scientific business ought all to be non-scientific men, will jeer at this statement, but it is, nevertheless, fatally true.

It is possible that, even if we had the science, the pedagogues would pay no attention to its principles, just as there are industrial chemists in London whose businesses are dwindling because they pay no attention to the science of chemistry. Pedagogy is in a worse condition than industrial chemistry, because chemical products can be easily tested as good or bad, whereas the pedagogic product is exceedingly difficult to test. The customer is the worst of judges. Those soul-destroying cheap schools described by Mr. Wells used to be very numerous; they are still, many of them, in existence. Every observant person knows of these places, to which small shopkeepers still send their sons, because they are genteel and cheap, and because Latin is taught, and perhaps French. Did any such parent ever object to the result of the schooling? Even when a boy has become a man, neither he nor his father knows whether his defects or merits are due to bad or good schooling. Please read Mr. Wells's book about Mr. Polly. Again, the reforms in pedagogy which, with Dr. Armstrong, I have been clamouring for during the last thirty years, would cause the best-known pedagogues to scrap all their machinery, and so to lose nearly the whole of their invested capital. Even when they are not influenced by the idea of losing money, these men cannot be made to believe in the necessity for reform any more than the Central African worshippers of hideous idols can be converted, for with just as much intensity do they worship the product of our present schools and colleges. The pedagogue is not alone in his false worship; this is the day of small men, common-place men, men manufactured like so many buttons, so that it is almost impossible for a great man to appear; everybody is compelled by custom or by law to go to school, and the school ideal is just as false and mean and material as any false religion ever was. Every clever man who has gone to a public school and to Oxford or Cambridge worships the system which has taken from him his spiritual birthright, his individuality, his initiative, his originality, his common-sense, his power to think for himself—yes, and I may say his belief in himself. He has become too much like a sheep, ready to follow the bell-wether; he is a man who has greatly lost his soul. Average boys leaving a public school all speak in the same way, in the same words, about anything. They are nearly as much alike as things manufactured by the same machine. An expert easily tells from what school a boy has come, because there is nothing left in his mind which is not common to the whole school.

The education given in England to boys until they leave school at twenty, and until they graduate at a university, is almost altogether classical: that is, founded on the language and literature of Greece and Rome. On the day on which I wrote this there was a report of an address in the *Times* which said that this study was the cause "of all imaginative aspirations, of all intellectual interests"; "it enabled men to appreciate not only Homer and Virgil, but equally Dante and Milton, Goethe, and Wordsworth, all the great thoughts of all ages and all lands, and to be awake to the movements of their own day." It said that this study made a man "a better man of business, a better lawyer, a better merchant, a better stockbroker, a less hidebound politician." "Those who would banish Greek or would make it the peculiar property of a select few, did a grave disservice to the whole cause of intellectual and spiritual life." The writer then described his own diligent reading in the train every morning; in the course of a few months he had read the "Iliad," the "Odyssey," the "Aeneid," five books of Livy, and the whole of "Catullus" and "Martial." It seems almost as if he must have all extant classical literature off by heart. He must have enormous satisfaction as he sits in the train looking at the quite common travellers who are reading about the affairs of the nation in English newspapers. I quote the above statements because they are typical. All our classical friends say that sort of thing. But I do not pay much attention to them, because I know that the greatest classical scholars only devote themselves to editing

some Greek text that has been edited over and over again. These men rave about the glory of youth and beauty as preached by the Greeks, but their enthusiasm is not shown in any practical way. We must believe that this enthusiasm exists, because these men tell us themselves that they experience it. But what is a fair man to say when he hears his friends talk of the beauties of Sophocles and Euripides if he knows that these friends never read Shakespeare or Jane Austen, or Goldsmith, or Dickens? I have not referred to the fact that classical scholarship leads to power and wealth in the Church and State, to palaces and baronies, to purple and fine linen. Leaving such things out of account, I have a suspicion that this worship of classics is like one's fondness for the rhymes, often rubbishy rhymes, that associate themselves with our infancy and boyhood, or like Johnson's belief that his wife was amiable and beautiful. It is even possible that the very best scholar is of but little use to the world. It would be easy to show that, since the sixteenth century, the classical pedant has done little but spoil the rich English language of our Bible. We want now a man like Bishop Pecock to delatinise our language.

Let us, however, consider a boy of another class—the boy called clever, say, one in twenty of the whole. At the age of twenty or twenty-one, stale and tired with the reception of ancient learning, of other men's thoughts, he gains a fine scholarship at the university, where he is supposed to be almost a free man, and all the use he can make of his freedom is to go on absorbing ancient learning, keeping his nose to the grindstone as if he were still a schoolboy. Treated as a boy from seventeen to twenty-one, he remains a boy till he is twenty-four, and he cannot help becoming a small-minded, though clever and learned, man, who fails to see that literature is no longer the possession of a small class. Yet if he had left school for the university at sixteen or seventeen, we might hope that university freedom and association with others and with learned men might have made him great, a great poet, a man of cultivated imagination, fit to become a great writer, a great philosopher, a great politician, a ruler of men. One of the curses of intellectual England is due to schoolmasters keeping men at school and treating them as boys to the age of twenty or twenty-one. They take scholarships as stall-fed cattle take prizes at agricultural shows.

Our famous writers had, like Burns, no school education, or else only a short school education. Boys went to the university too early after the Renaissance, and Bacon entered Cambridge at the age of thirteen. Shakespeare, thank God, was only at a grammar school, and is supposed not to have completed even that short course of school work. Even Ben Jonson, who was so proud of his learning and rather scorned Shakespeare for his "small Latin and less Greek," had only a short school education. Phineas Fletcher went to Cambridge at sixteen. Massinger went to Oxford at eighteen. Of the school time of some of our most original writers we have but little information, but that it must have been short we have indirect proof. Beaumont's first play was produced at the age of twenty-one. Waller entered Parliament and wrote his first poem at eighteen. Dryden went to Oxford at seventeen. Milton went to Cambridge at seventeen. Addison went to Oxford at fifteen. The whole of Pope's school education was four-and-a-half years. Swift went to Dublin University at fifteen. Goldsmith, after a most erratic school time, entered Dublin when he was fifteen. Our present school system is to keep a boy with his nose to the classics grindstone from the age of eleven to the age of twenty, and copies the German system. The result is the same in Germany and England. Genius is very common in both countries, but 99 per cent. of it is destroyed by the schools. It is, however, when we come to study the average boy—nineteen in twenty of all boys—that the system looks most devilish. In Germany it is worse than in England. There even the average boy submits, and plods hard all the time, because there is a great reward for him—a diminution in his time of military service. Well, the result for the average German boy is that he becomes stupefied, dull, and loses all initiative. The average English boy gets much less of these evil effects, because he neglects his schoolroom work and keeps his mind active and his soul alive by means of football and cricket. It is from this great characteristic, that knowledge and wisdom come from doing, and not from abstract reasoning, that the British race rules the world. We learn all that induces common-sense from observation and experiment. I often used to observe that a boy whose face was attractive because of its brightness and intelligence in the cricket field, seemed when he entered my classroom as if an isolating veil of unintelligence suddenly covered his face. He had settled for life that he could not understand the classroom work, and he refused to make any more efforts. Even the clever boy's soul is to some extent protected by his sports, so that in every way less harm is done in England than in Germany. Still, the system produces, even from clever boys, only clever, dull men, fit to be barnacles in the public services. The system may be said to give a good training for lawyers—the necessary clever kind of lawyer of the Law Courts and Chambers who is mute in the House of Commons.[1] But it destroys the higher qualities of men and makes them narrow. It ought to be remembered that Lord Somers was the only great lawyer who was also a great man. Poor boys cannot get this training unless they are so unlucky as to get scholarships, or are induced to attend university extension lectures; and it results that nearly all our best writers, writers with imagination and originality and initiative and individuality, have been boys of the common people. Although poor boys are most frightfully handicapped for the race to distinction, I do not think that the poor child is much handicapped by mere heredity, for he is naturally nearly equal to a boy of the highest lineage. Natural selection up to the time of the first great civilisations, when there were comfortable houses and palaces—say, 100,000 years ago—together with the effects since then of revolutions and wars of conquest, involving slavery of the conquered, have created a wonderful equality among the individuals of mixable races.

For the average boy at a public school the school work is a terrible uphill grind all the time; a soul-destroying, stupefying business, so stupefying that he makes no complaint, he merely suffers. He feels that he is a failure, learning nothing that can be of spiritual or material value to him in his future life. Of course, he can pass examinations; anybody can be crammed

[1] The acuteness of a lawyer in finding the meaning of a document is very wonderful. Almost any mental power can be cultivated to such a very high degree that it almost seems diabolical. A trained person after passing a shop window rapidly is able to describe every object in the window, although the objects may be very numerous and curiously different. Yet this same man may not be at all clever in other ways. In patent cases a clever judge takes in the most elementary scientific knowledge with very great difficulty. The readers of the hundreds of newspaper articles of any morning—as like one another as herrings—are awed with their display of culture, of depth of thought, of knowledge, and with, what is more astounding than anything else, an infinitely perfect Oxford polish. Watching the performances of an Oxford man of letters is like watching a good billiard player or a skilled musician. His mind is filled with the thoughts of other men, pigeonholed ready for use. It is extraordinary that a man can have been so educated as to be a good debater, to be able to make a fine speech, that he may have taken a degree at Oxford, that he may have passed examinations in classics, philosophy, and mathematics, and yet be exceedingly ignorant, illogical, and unscientific.

to pass an examination, but after the examination he forgets what he was supposed to have learnt.

The present system of education is to be condemned for other reasons. It is exasperating that all the most important, the most brilliant, the most expensively educated people in England, our poets and novelists, our legislators and lawyers, our soldiers and sailors, our great manufacturers and merchants, our clergymen and schoolmasters, are quite ignorant of natural science; and it may almost be said that in spite of these clever ignorant men, and men like them in other countries, through the agency of scientific men, all the conditions of civilisation are being transformed. I do not think that a fact of this kind would have been neglected by the philosophers of Greece (who scorned to know any other language than their own) or the learned men of Rome, but when some of us direct attention to it and its neglect by modern philosophers we are sneered at as Philistines. It is a curious kind of culture which scorns the lessons of history, the study of man in his relation to nature, the study of the enormous new forces which are now affecting the relations of nations to one another. How many of our rulers know the astounding fact that the cost of the most unskilled work done by man costs 1000 times as much as when that work is done by a steam-engine? Hence it is that the steam-engine has given means for leisure and high culture, yes, and low culture and decadence, to hundreds of people instead of units. And the steam engine enables rulers to spend 100 times as much money on soldiers and sailors and ships and munitions of war as they did 200 years ago.

The university man thinks that he can get some knowledge of science by reading, but without laboratory study he is like the man who said "barley" when he wanted to escape from the robbers' cave and ought to have said "sesame." Do you know the ballad about Count Arnaldos, who envied the old helmsman his weird and wondrous powers?

> "Would'st thou," thus the helmsman answered,
> "Learn the secret of the sea?
> Only those that brave its dangers
> Comprehend its mystery."

I know that the ordinary university man thinks, like the wistful Count, that he can get all things easily or by mere reading. But, in truth, to read the "Origin of Species," or treatises on astronomy or physics or chemistry, is a misleading performance unless the reader brings to the study that kind of mind which has been developed already by his own observation and experiment.

The university man, ignorant of science, becomes a ruler of our great nation, his duty during war and peace being that of a scientific administrator, and without turning a hair he fraudulently accepts this important duty for which he is utterly unfit. The gods must surely laugh when they see these rulers of ours gibing at scientific things, giving important posts to non-scientific men who scorn and obstruct the scientific men who are under their orders. If Oxford scholars were merely like so many monks in their monastery, living the lives and following the studies which they love, I would say nothing. The revenues so used up are, I think, of no great importance to the country, and busy men elsewhere can only be benefited in knowing that at Oxford and Cambridge there are these lovely lamaseries where men are living in serene air apart from the struggles of the world, living what they think to be the higher kind of life, that of the amateur copying the lives of the scholars of Constantinople before they were so mercifully scattered in 1453, copying the meditative ways of the divines and hermits of the fourth and fifth centuries. Unfortunately the Oxford hermits have by a series of accidents become the rulers of the greatest Empire that the earth has ever seen, and it is very obvious indeed through many other things than the starting of South African wars that they are unfit for their job.

If our rulers were like savage chiefs they might possibly give equal chances to candidates for posts; but unfortunately it is as if our leaders possessed great *negative* knowledge of natural science, and as if a man's chances of being appointed to a scientific post or of having his advice listened to were in inverse proportion to his scientific qualifications. Scientific men look around them and see that everything is wrong in the present arrangements, but they also see that it is useless to give advice which cannot be understood by our rulers. And, indeed, I may say that when by accident a scientific man is appointed on a committee there is a negative inducement for him to do anything.

Many men enter the Services by examination, and it is always through cramming that they pass. In some cases the examination is supposed to be in science. In truth, the scientific habit of thought, the real study of science, the very fitness of a boy for entrance to the service, would unfit him for passing these abominable unscientific examinations. For some army posts, further scientific food is provided by the Government for the classical or modern language or science dummies after they enter the Service. If one wishes to hear how evil this system of pretended education is, let him ask the opinion of some of the professors who are condemned to help in carrying it out. The whole system is foolishness from top to bottom, and the men prepared by the system cannot see how abominable it is, even when they are afterwards trying to improve it; well-mannered mediocrity is everywhere successful and reproduces itself.

I have been dwelling upon the consequences of letting aristocratic university men who are to be rulers of the country have an education which involves no study of natural science. Besides these men we have a larger number of middle-class men who will succeed their fathers in the management, not merely of landed estates, but of much more valuable estates in the manufacture and distribution of things. With them there is the same contempt for books, for learning, and the same absence, not merely of knowledge and of natural science, but of those scientific habits of thought and methods of approaching problems which experimental research tends to produce. These men become the owners of factories the spirit of which ought to be scientific research; the competing factories in Germany, France, and America are run by men of scientific method, but our owners discourage reform in every possible way. The rule of thumb of their fathers and grandfathers is good enough for them. Their factories are so badly arranged that the works cost of any manufacture is twice what it ought to be and the time taken is twice as great. They take eagerly to all sorts of quack remedies for bad trade; they are the easy victims of fraudulent persons. These are the men who discourage all education in the people employed by them, managers, foremen, and workmen. They are what I call unskilled workmen—that is, unskilled owners of works—and it is the university and the whole system of their education which is to blame for their unskilfulness. It is astounding how quickly unskilled owners of works are being eliminated, but there is a new crop of them every year. The want of education of these men is very harmful to the country.

But I get too angry when I think of what our universities might do in the great world of natural science and of the futility of almost all their studies. And this anger is greater when I think that the universities rule the schools. The general higher education of the community is being altogether neglected, the general culture of professional men is being neglected; and in

the case of professions involving applications of physical science, useless obligatory subjects are insisted upon, so that for these professions the university is a harmful institution. Medical students have so much hard work in various kinds of grammar subjects required for matriculation that they must be forgiven for their utter ignorance of natural science. But an outside Philistine may also be forgiven when he suggests that the whole country might benefit if the school training of medical students put them more in sympathy with scientific discovery. It is a well-known fact that there are medical men in lucrative practice, said to have the highest university qualifications, who tell you frankly that they do not believe in bacteriology!

A great many young men from the secondary schools are now entering the engineering profession. By engineering I mean any kind of applied physical science. Every important town in Great Britain has established at least one great technical college at large cost in building and apparatus, with staffs of professors and teachers (always badly paid), and it is found that for their first two years the students have to be kept at great cost to the country learning those simple principles of science which they ought to have learnt at school. It is found that they are not only ignorant, but they have none of the habits of thought and scientific method which school laboratory work induces. The clever ones, if they leave school at seventeen, recover from the effects of a school education which prepared men only for being lawyers or clergymen; but the average man finds that he has been prepared only to be a hewer of wood and a drawer of water to the real engineer. It is found in most cases that the successful students are those who have attended primary schools where no boy is compelled to learn any language other than English, and where every boy does laboratory work in mathematics and natural science. There can be no doubt that poor boys have now an enormous advantage over the sons of rich men, for even when the fees of the day classes are large the evening class fees are small, and the poor boys attending the latter are getting to be very fit for higher study in natural science.

The English school system has outlived the medieval conditions which produced it. In old days the only way to knowledge was through Latin: all writing was in Latin. The result then was pretty much what it is now; lawyers, clergymen, and schoolmasters had to know some Latin after school life; the average man forgot anything he had learnt. A few very clever men did read, but the average monk or priest was a very ignorant person.

English people know the worthlessness of the public school system in the mental training of the average boy. Why, then, do they submit to it? However conservative they may be, they would not submit to this worthless system merely because it is hallowed by a history of five hundred years.

The fact is, this worthless system continues because in some occult way it seems to have a connection with something of real importance, *public school form*. There is really no connection. When, in my youth, I was a master at one of the great English public schools, like everybody else, I was a frightful prig in regard to public school *form*. Eton form or Harrow form or Rugby form or Clifton form was the thing at each of these schools which was thought to be of more value than anything else in the world. Dr. Arnold, of Rugby, taught the trick of manufacturing it. It is in itself a splendid thing. The public school boy is trained in self-possession, modesty, cleanliness, truthfulness, and courage. At school his health in body and morals is all-important. He learns to lead and also to obey. But the average resulting man is exceedingly ignorant; he neither reads nor writes, and he has little reasoning power except what his sports have developed. This form is essentially aristocratic. It is based on superiority of position or birth or caste. A man's place is fixed, his attitude to people of higher or lower rank is fixed. He needs no self-assertion, and he cannot become a "bounder," that is, a "cad"; but in Thackeray's sense he is usually a "snob," and in various directions he may be a *prig*. By prig, I mean a man who cannot get outside convention and so cannot exercise his own common sense. One defect is that public school form when combined with poverty cannot make much money by its own ability, and if it does not starve it must join the valets or the grooms. Its strength lies in convention and habit and the belief that poor people are not men but a lower kind of animal who may be pitied as we pity a suffering dog. Such pity can never raise the people or reform abuses. In the Middle Ages young gentlemen of England had the same sort of education. It was probably best in Plantagenet times, when indeed a well-trained young gentleman was not only very healthy and courageous, but he had not much chance of becoming lazy. A man was proud of his heavy armour, and he was trained to act vigorously when carrying it. They were chivalrous to each other, but, alas! to people outside their own class they were cruel. The Black Prince is typical; think of his courtesy to King John of France, and then think of his destruction of the persons and property of all the peasantry in those large regions of France which he covered with his marauding soldiers. This kind of chivalry, which is never exhibited to a lower class than one's own, has its beauty, but it does not suit a democracy; it requires that there should be a lower class than its own. The Spartans needed their helots. The Southern planter in America had fine manners, but he could not have cultivated them if there had been no slaves and mean whites. It is a well-known fact that some years before the Civil War in America it was seriously proposed by prominent Southerners to make slaves of the "mean," that is, the poor whites. The chivalrous Andrew Fletcher of Saltoun showed but little knowledge of his countrymen when he formed his plan for reducing a large part of the working classes of Scotland to slavery. Public school form may sit not unhandsomely upon country gentlemen or any rich men who have many servants or tenants or other dependants, but it does not sit at all well upon poorer men, for it puts them out of sympathy with people among whom they must work. It is heartbreaking when associated with the poverty of a man looking for work in places where he has no influential friends, as it is nearly always associated with illiteracy and want of wisdom, with helplessness and with disinclination to learn. Nobody doubts that a modern country gentleman is much more polished than Squire Western or Squire Lumpkin, but he has much the same opinions and forms them in the same way. The manners of a young officer are certainly superior to those of Ensign Northerton, but he is in much the same state of ignorance. Nineteen out of any twenty young officers, if sent to the top of a hill to observe things, cannot write an account of what they see, and they can hardly describe in spoken words what they see, because their vocabulary is too limited. They cannot write a simple letter in English, although they are supposed to have learnt English in the best way, through Latin. On the day when I wrote the last sentence I happened to see the following statement in the *Times*. It is from an unimpeachable authority, a man whose business it is to teach young officers how to fill up official forms. He was speaking of their ignorance and describing a special instance: ". . . a young officer who shut himself up in a room to write

a letter. At the end of two hours he was found sitting, very pale, before a large sheet of paper, on which he had written, 'I say Cox '—' Cox ' being the name of the regimental banker." He did not know even how to begin to write a letter.[2]

We ask the schools for mental power as of old one asked for bread, and they give us a stone. No doubt public school form is a beautiful stone, a diamond; but we want some bread as well, even if it were only in the Falstaffian proportion of bread to sack. For my part I do not see why the average boy at school should not have reasoning power and a love for reading and knowledge as well as good manners, and this is why I ask for a great reform in our schools. We want from the school what nature has not been accustomed to give, and what home life cannot give, the development of the intellect, and the school fails to give it in ninety-five out of every hundred cases. The great danger in school life is that it may hurt individuality, originality, because a boy, however harum-scarum, is naturally conventional and imitative. Good form comes easily, therefore, and the master is more than satisfied, he is proud. He often speaks of it as *character*, but he is quite wrong. Character comes from home life, not from school life, which indeed is rather antagonistic to character. It comes from contact with fathers and mothers, brothers and sisters, relations and friends. School life tends to induce a contempt for the lower classes and a slavish admiration of the upper classes, which is altogether wrong in a democracy, and can only lead to evil.

It always happens that the real education of the average man begins when he falls in love and sees the necessity for writing love letters. He must have spent many years of worry at school and passed examinations in Latin and mathematics, perhaps in French or German, in geography, and many other subjects, all taught in water-tight compartments, yet he is quite illiterate. If he has been slightly higher than the average boy he is able occasionally in after life to quote one or two tags from the Latin grammar and to say that he thought he remembered something of the *pons asinorum*; he is also fond of using the expression, "the unknown quantity *x*," because it shows that he once worked at algebra. A Premier of Great Britain who had sent out a great military expedition to Cape Breton expressed great delight afterwards when he suddenly discovered that Cape Breton was an island. Chancellors of the Exchequer have shown themselves to be quite ignorant of the simplest arithmetic. A very successful Cambridge coach told me that it is quite common for the father of a pupil to tell him that he does not wish his son to get a good degree. Generalisation is always dangerous, but I think I am safe in saying that Englishmen of the higher classes do not believe in education. They believe in what they call character, which always to them means public school form, and they believe in mental mediocrity, which in most cases means mental inferiority. This gives one explanation of the persistence of the public school system. The man who remembers his years of dull school classroom routine with no intellectual result is not likely to be enthusiastic over the education of his son.

Unfortunately all secondary schools try to copy the public schools. They also aim at teaching good form, mainly by magnifying the importance of football and cricket. To differentiate themselves from the primary schools, they compel every boy to learn through Latin. And all this they do at a rate which suits the pockets of the lower middle-class parent. It is a poor imitation of a system only one part of which is worthy of imitation.

I can understand why Tom Sawyer and his friends, when they started their gang of robbers, initiated them through passwords and a ritual. That was for "side." The gang did not consist of pirates or robbers; they were innocent young boys, and their passwords and ritual were the essence of the romance of the thing. Latin for the average youth seems to me to be merely grown-up Tom Sawyerism, and is allied in obvious ways to the worship of Mumbo-Jumbo. It used to be that the use of fur on clothes was reserved for the higher classes. At another time gentlemen only were allowed to wear swords. In China and Japan certain buttons and coloured dresses indicated certain rank. In our own time there are fashions of slang which distinguish the smart set of society. The survival of Latin and Greek is very much the same sort of thing. It has no more to do with education than the two hind buttons of our coats or the wigs of our judges have to do with convenience. The classics ride us like Sindbad's old man of the sea. All over the British Empire a well-educated man cannot become a professional man of almost any kind unless he pretends to know something of one or more dead languages, such knowledge being of no essential value to him. It is something like what the old Test Act imposed upon us; for 130 years a British citizen perfectly competent to fill the highest posts could not take upon himself the smallest kind of public work unless he could swear to a certain formula. Most of the numerous students of a very important school of mines refuse to take their B.Sc. degrees because they are wise enough to refuse to learn Latin. The mine-owners are wise enough to engage these men if they possess only the college diploma, although they have no degree. There is scarcely one mining engineer holding a university degree in the country that I speak of. Indeed, I may say that only a few mining engineers in Great Britain hold a university degree, and this is for the same reason.

If there is any particularly useless, poor, genteel clerk you will find that his son must be taught Latin. If there is any little township in a new country where everybody is ignorant, the schoolmaster must teach Latin. Any cheap schoolmaster, knowing nothing, worth nothing, will, you may be sure, say that he can teach Latin. If there is a particularly illiterate bar-room loafer in the town who never reads books or newspapers you will find that he has a stock-in-trade of perhaps three Latin phrases which keep him provided in beer.

Do you know why Portia the Maid of Belmont remained so long unmarried? It was because her suitors assumed that the golden language of conquest was Greek and the silver language was Latin. If you read between the lines you will see that this is what Shakespeare meant. His leaden casket signified the English of Belmont-cum-Stratford-on-Avon.

The worst of it is that the average boy who has done almost nothing else than Latin and Greek at school gets absolutely no love for the classics; he never reads a Greek or Latin author after he leaves school. He might enjoy them in translations, but he hates their names, and even if he did not it would never enter his

[2] The Report of the Commission on the Education and Training of Officers of the Army (1902) is well worth study. Dr. Maguire, the most experienced coach, said, as a witness:—"Latin, as taught to the average schoolboy is pure waste of time, and does not develop intelligence or tend to breadth of culture in the least or facilitate the acquisition of modern languages." . . . "The prominence of ancient classics in English schools and the large proportion of youthful years devoted to failure in regard to them explain the stupidity and incapacity of their pupils as compared with the same class of persons in other advanced communities." . . . "They [classics] are kept in such vogue to suit the convenience of languid schoolmasters who can teach nothing else, and for no other reason whatever." He spoke of "the absurd anachronism of lazy and costly schools, which rendered so many of us ignorant of the very subjects which are generally useful and interesting." He said: "but our educational system all round is utter folly at best." Speaking of English Universities, "the whole system is a grievous absurdity." "'Society' and snobbery are the curses of England."

head to read a "crib." Surely this is the natural effect of the schoolroom routine.

Following that article in the *Times* newspaper, referred to above, in a discussion, the secretary of the Association for Improving the Teaching of Latin said, "Out of the vast number of boys who learned Latin only a few reached the stage when they could read the classics with any pleasure. A still smaller minority continued their classics after they had left school or the university. The great majority left school with very little, if anything, as the result of years spent in the study of the classics." The next speaker said that the reforms suggested "were based upon the assumption that the present method of classical education was wholly bad. He did not agree." Nor do I agree. I think that if there is one subject that the ordinary public schoolmaster can teach it is Latin. I take the first statement as right, however. I have always said so, loudly, to an unbelieving world that thought me prejudiced, and here we see a lover of the classics inadvertently supporting me, and surely every fair-minded schoolmaster must agree with him, at all events concerning the average boy. It is not the method of teaching that is wrong; it is merely that Latin as a school subject for the average boy must be altogether condemned. It takes from him all interest in every kind of literature; it makes him dislike reading. We must have some compulsory subjects, and I think that any boy may be taught any subject —to some extent; but we ought to have as few of these compulsory subjects as possible, because any subject may be found very difficult by certain classes of intelligent minds. And it is surely ludicrous when a clever mathematician, well read in natural science and fond of English literature, is plucked for his degree because of his poor Latin or Greek. I knew a case where the first classic of his year would have failed to pass his "Little-go" only that special arrangements were made to let him through his mathematics easily. My own career was nearly ruined because I failed in a French examination.

Before a student enters a university he has to pass a matriculation examination, so that we may be sure that he is fit to follow any of the courses of study. In medieval times the one compulsory subject was Latin, because all the literature known to students and teachers was in Latin, all lectures were delivered in Latin, all teaching was in Latin. Consequently in some Oxford colleges a man was fined if he spoke in any other tongue. Then came the time when there was still no English literature, and not only was the best literature in Greek, but Greek was the only approach to natural knowledge, so Greek also was compulsory, and so it has remained to this day—to this day when English literature (including translations) is of greater worth than any ancient or, indeed, any other modern literature; when all teaching, all lectures are given in English, and when our English knowledge of natural science is not only infinitely greater than anything possessed by the ancients; but it enables us to say that the ancients were hopelessly wrong; when nobody but the official university orator or some traveller ignorant of the language of a foreign country speaks Latin and then speaks rather the language of Stratford-atte-Bow than the Latin of the City of the Golden Shields. The men of the City of the Violet Crown were not handicapped by being compelled to learn any other language than their own, to waste their time on mere words; "they were engaged in pursuits of a higher nature, in acquiring a knowledge of *things*. They did not, like us, spend seven or ten years of scholastic labour in making a general acquaintance with two dead languages. These years were employed in the study of *nature* and in gaining the elements of philosophical knowledge from her original economy and laws." The above quotation is from the Langhornes' "Life of Plutarch," and it is particularly valuable as expressing the views of two great classical scholars.

I would make a knowledge of Latin or of Greek compulsory only on students of certain subjects, and the professor ought to impose the condition, not the university. Again, students of certain other subjects ought to know one or more foreign languages, and, indeed, it seems to me that the professor in each subject has a right to insist on his students having certain special knowledge before they enter upon a study with him. But to enter the university, surely the compulsory subjects ought to be as few as possible. It seems to me that the most important thing is to make sure that every student has had an early education through his own language—English; that he should be able to write an account in English of anything he has seen; should have some acquaintance with what are called English subjects, such as geography and history, and the principles of natural science, and the power to make simple computations. All the teaching is to be in English, all his companions speak English; there are good English books on all subjects, there are English translations of all the good books that have been written in foreign languages. So abominable do I think *compulsory* Latin or Greek or French or German that I believe a primary school to be a much better school than any other for a boy if he is fitting himself for any profession in which applied science is important. At present English is not taught properly in any British school. The teachers are all classical men, who are very careful when they write Greek or Latin and exceedingly careless and slipshod when they write English. We might easily write a fairy story about three sisters—Greek, Latin, and English—and call it "Cinderella." The language of the greatest Empire known in history, the Empire of the English-speaking peoples, is not taught seriously in any part of that great Empire. It is shocking to get from a great classical scholar a letter with misspelt words on every page, every sentence being ungrammatical. When will our good modern writers tell us how English composition may be taught to ordinary folk?

I want you to understand that we have established some fundamental principles in our science: (1) A subject must interest a pupil. (2) A man who trains dogs or seals or bears or other animals makes a close study of their minds. In the same way we must recognise that one boy differs from another, and study the mind of each boy. (3) If a boy is not very receptive of an important subject we must do our best with him and try to settle what is the minimum with which we ought to be satisfied. Only a few subjects ought to be compulsory on all boys. (4) There are two classes of boys unequal as to numbers, (*a*) those fond of, and (*b*) those not capable of abstract reasoning. (5) Another two classes are (*a*) those fond of, and (*b*) those not fond of language study. (6) Every boy may be made to write and read in his own language and he may be made fond of reading. (7) The average boy's reasoning faculties are most surely developed by letting him do things. That is, for example, through his sports, or through wood or metal-working, or gardening, or experiments involving weighing and measuring. Through the last of these he learns to compute. A boy of eight learns decimals in an hour if he weighs and measures, whereas by the usual method of teaching he is ignorant of decimals at the age of fourteen. A boy learns whist very quickly if you seat him with three other people at a table with a pack of cards; he would not learn in a month if he had no cards. Would you teach a boy to swim by mere talk? (8) Every boy must get a good deal of personal attention. (9) However good a system may

be there can be no good results if the teachers are cheap; cheap teachers are usually stupid and overworked. Men in charge of schools and colleges never seem to learn this. The market price must be paid for a capable man. (10) Fairly good results may be expected from a good teacher, even when he is compelled to work on a bad system, but really good results can be obtainable only from a good teacher with a good system.

I need not go into details about all these principles, but I should like to dwell presently upon a few of them. At the beginning of this address I spoke of the obstruction to great necessary reform—too much antiquated machinery to "scrap." Most schoolmasters will admit the necessity for reform in the case of the average boy, but they say that parents are opposed to the reform. Unbelief in education for the average man is so general among the higher classes that I am afraid we shall have no reform unless some great national disaster causes conversion. There is a lesson for England, and, indeed, for all European races, in the recent history of Japan. The old structure of Japan was in many ways beautiful, but it proved to be without physical strength. Its extreme weakness proved its salvation. Even the teachers of ancient classics saw that for strength it was necessary to let scientific method permeate the thought of the whole population. And now, at the end of the first chapter of Japan's modern history, we find a nation which can not only defend itself, but which retains all of its spiritual life which was beautiful. Every unit of the population can not only read and write, but it is fond of reading, and its education did not cease when it left school. It is getting an increased love for natural science, so that it can reason clearly; it is not carried away by charlatans; it retains its individuality. One result of this is that in time of war Japan has scientific armies. Not only are its admirals and generals scientific, but also every officer, every private is scientific. Everything in the whole country is being developed scientifically, and we Europeans, hag-ridden by pedantry in our schools and universities, refuse to learn an easy lesson. At present we do not even ask what is meant by education or what education is necessary if a particular boy is to be fitted for his life's work. In 1902, when I was president of Section G, and in opening a discussion on the teaching of mechanics at Johannesburg in 1905, I gave my views as to the teaching of a young engineer, but they apply also to the teaching of nearly all boys. These views have been commended by experienced engineers and teachers. To understand me it is first necessary to try to cast away prejudices, and this is especially difficult if one has a pecuniary interest in education. The student of almost any other science than education cares for nothing but the truth; even when he has committed himself to a theory and his good name or credit is at stake the rule of the game is perfectly well known and must be adhered to. The student must not neglect fact or pervert fact; he must be quite fair. The student of physical science sees at once whether or not he is playing the game, because the coordinates are few; there are no complexities, such as we find in our own life problems. This also is why the study of physical science is so good in causing boys to reason, for reasoning can only be taught by constant practice on simple matters which one thoroughly comprehends. Consider a boy's views about ordinary affairs. He is downright. A complex thing must be greatly simplified to him. His painting is in black-and-white; there is no delicate shading in his picture. He never sits on the fence; he is never a trimmer. An historical character is awfully good or awfully bad, very clever or very stupid. A boy is, in fact, cocksure about everything. He is incapable of reasoning about complex things. And when we try to teach him to reason about simple things we must be quite sure that they really are simple to him, that he understands them. For example, many educationists say that the study of geometry is just right for a boy. Well, yes, for 5 per cent. of all boys, boys who can take in abstract ideas. They take to Euclid as a duck takes to water. But for the other 95 per cent. geometry is very hurtful, because unless they continually experiment with rulers and compasses they do not understand what the reasoning is about. In ancient times only very old and exceptionally clever men were allowed to study geometry. We now assume that it ought to be an easy study for the average English boy. Generation after generation we stupefy the average English boy with demonstrative geometry, and we call him a duffer so often that he thinks himself a duffer, and even his mother thinks him a duffer, and, indeed, we have done our best with geometry and Latin to make him a duffer. Only for his football and cricket, which teach him to reason a little, he would become a duffer. And yet in my opinion if this average boy were properly taught in school he would prove to be very superior to the boy who is usually called clever. The schoolmaster calls a boy clever because he is exactly like what the schoolmaster himself was when a boy; but I am afraid that I place little value on the schoolmaster's cleverness, whether as a boy or a man. Reasoning can be taught through almost anything that a boy does, but more than all things through his experiments in natural science. Formal lessons on reasoning, on logic, are utterly useless, and I may say that set lessons on almost any subject are utterly useless for the average boy.

Milton's poems are greatly praised. Well, I am not going to say a word against the people who talk in public about the most wonderful epic in our language and who never read it; but how many people have read Milton's magnificent prose works? Milton first taught me the true notion of education, that the greatest mistake is in teaching subjects in water-tight compartments. It is the idea underlying one of the most instructive books ever written, "Sandford and Merton." When teaching a subject, teach all sorts of other subjects as well. If Mr. Barlow's boys were interested in astronomy he showed them stars and planets through a telescope for a night or two, but he gave them no stupefying course on astronomy. He gave them stars and the solar system just as long as they were interested. He used a globe as well as mere maps in teaching them geography and history, but the soul-destroying idea of a course of study on "the use of the globes" did not commend itself to him. They walked over the fields and took an interest in trees and flowers, but he gave them no stupefying course on botany. When he gave them a lesson on English grammar or literature he taught them at the same time the geography and history and the fairy stories of their country. How can a man give a course on grammar or geography or history or anything else without diverting his talk in an interesting way to other subjects? What is so tremendously important about natural science laboratory work is that a student must be thinking all the time about the same matters, not from one but from ten interesting points of view. He is not merely observing, he is measuring, he is computing, he is reasoning; he has to write out descriptions of what he sees and does, and he thinks then of his spelling and grammar; he has to sketch; he has to read books about what other people have done before him on the same subject, and also

for statistics. He learns the value of a bit of work done in a clean honest way, and when he gets some more experience he glows with the feeling that he has really added to the knowledge of the world. He is a discoverer, and he feels the emotion of Cortez! It is marvellous the alteration which has occurred in the mental attitude of the common average boy. Instead of feeling that he is a degraded slave he feels the emotion of his childhood returning to him. He once made the great discovery at the age of six that the back garden was inhabited by fairies and lions and Indians and pirates. He was the Caliph Haroun Alraschid for a while. And now, after a wretched life at Latin and Euclid, a new revelation is vouchsafed to him, and as he gathers years he finds that nature is placidly willing to let him steal her secrets little by little, one by one, secrets that are gradually changing men from the bewilderment and spirit possession of the Middle Ages; so that at length he enters into complete communion with nature and rollicks with her, and quarrels with her, and loves her more and more until he dies. And his reasoning power has been growing all the time, so that more and more he understands complex things, for, after an experimental study of story-books, he probably entered the kingdom of Shakespeare at the age of fourteen. Things requiring memory can be learnt only in early life—weights and measures, the multiplication table, languages. He knows games involving spelling. But, over and above all these, he has from infancy repeated all sorts of poetry long before he could enjoy much more of it than the jingle of its rhyme.

Education consists in the development of a man from his earliest day, and does not cease until he dies. Any thoughtful man must see that there is no science so important as that of education, the preparation of children of this generation to be the citizens, the rulers of the country, in the next generation. The whole future of our Empire depends upon the education of the children. By the study of this science we hope to improve teaching so as to make future citizens not only to have more knowledge and more skill, but to make them wiser than the people of the present or the past.

Early training determines what later training ought to be. Let us consider what the early training of a boy ought to be. In his very early days nature has provided that his education shall proceed very rapidly by observation and experiment, and the only teaching needed is through careful nursing and affection. He teaches himself, and he loves to learn. He ought to get toys not too realistic, for he loves to weave romance round his toys, but still things to observe and experiment with. He has most complex problems in physical science when he is only a few weeks old, the solution of which involves much labour, but it is pleasant labour and he is happy. And he will remain sweet-tempered and happy and unspoilt if there is real affection from his teachers. If, however, somebody teases him by playing practical jokes, or if a selfish mother who was unreasonably kind to him yesterday is unreasonably unkind to him to-day, he gets, because of his reasoning power, a sense of injustice. Man, woman, or child with a sense of injustice may be said to be possessed of a devil. During the first six years of a child's life the creation of its power to reason is more wonderful than anything else, and this reasoning power comes altogether by observation and experiment. An affectionate parent easily finds methods of helping nature in this process. The unspoilt boy of six years seems to forget nothing that he hears; he has gathered a most wonderful vocabulary; he knows endless nursery rhymes and simple poetry; he is as active and adventurous as a kitten, and everything he does is cultivating his senses. This is the time when he fills the smallest playground (which to grown-ups seems bare and desolate) with giants and fairies and Indians and pirates, with forests and mountains and rivers and oceans. His imagination is so extraordinary that the most uncouth creation of his own gives him exquisite pleasure. Why do I dwell upon this stage of a boy's development? Because it has been so perfect. Nature has learnt to do this to children during perhaps hundreds of thousands of years, and it has been the most important time of a boy's life, the time when, if parents will only give the boy their love and greatly let him alone otherwise, he develops mentally more than during all the rest of his life. Speaking broadly, he has done nothing in all this time except what nature and affection made pleasant to him. I have studied the science of education and practised the art of teaching all my life, and I say that all our failures are due to our neglect of nature's methods, and our schools destroy the good effects which nature has produced.

As a rule I do not like to be told that certain subjects must be compulsory, but surely every child of eleven must have some such qualifications as these: (1) The power to speak and read and write in his own language. (2) To be able to do easy computation. (3) To have an exact knowledge of the simplest principles of natural science from his own observation and experiment. I think that every observer must acknowledge that these powers are possible for almost every boy of eleven. Some of us have for many years been endeavouring to show how the child of six may acquire these powers by the age of eleven if nature's methods—that is, kindergarten methods—are followed. For example, he plays at keeping shop, selling or buying things by weight and measure, and paying or receiving actual money and giving change. He weighs and measures with greater and greater accuracy as he makes experiments in mechanics and heat and chemistry. Every boy is fond of stories, and if treated reasonably is easily induced to learn to read. Reading aloud is easily made a pleasure and a habit, and so the boy learns to speak properly. Any boy whatever will become fond of reading if the people about him are fond of reading: I state this as a fact which I have investigated. A boy who is fond of reading gets later on to know the value of books and the use of books, and he will go on educating himself until he dies. Any attempt at coercion, unless it is the very gentle coercion of a person whom he loves, is fatal; even coaxing is not always good. He assimilates knowledge from everything which he does, and therefore he ought to be induced to do things which not only keep him healthy, but which give him knowledge and teach him to reason. Do you remember how angry Lanfranc of Bec was at the idea that any pupil could be *forced* to learn; he said "it turned men into beasts." I speak to you who love children, who love young people, who know that there is scarcely one child in a hundred, even among rather spoilt children, who does not love to do his duty.

Under the best and most loving of teachers a lonely child has enormous disadvantages, but these can generally be remedied. The usual mistake is to send it to a large school. If it is merely a day school there is no great harm. But no child under thirteen ought to be sent to a boarding school unless it is a small school and the master and his wife have a love of sympathy for other people's children. There are such people in the world, God bless them! but they are not numerous. They are so few that we must return to nature as the best of teachers. The time is coming when a child's own father and mother will have much more knowledge and wisdom than they have now, and they will refuse to give up to others the doing of their highest duties. It is at present not sufficiently recognised that

the most important duty of the parents is the education of their children. At present, men who are building up fortunes are too busy to think of their children, and so we find that the sons of Lord Chancellors and other successful men have been marrying chorus girls and squandering those very fortunes to which their education was sacrificed. Of course, if parents are uneducated, and therefore selfish or otherwise foolish, any kind of school may be better than home for their doomed children. It is one of the great advantages of poverty that the children go to day schools and they keep in touch with home life. If the day school is really a boarding school as well, it will be found that there is always a differentiation in favour of the boarder, which has a very bad caste effect, just as the "modern-side" boy of any public school suffers in character because he is of a lower caste than the classical-side boy. It is usual to remove a stupid classical-side boy to the modern side, and every boy on the modern side has a sense of injustice. The work of the modern side ought to be much the higher, but it is always badly done because the atmosphere is altogether bad.

It may be said that I am only destructive in my criticism of public schools. I think it will be found that I am also constructive, although I acknowledge that my sketch needs much filling in. Well, can much more be done in an address lasting one hour? I will now try my hand at a little filling in. I have no objection to the existence of classical schools something like the present for boys who are fond of classics. The average boy will not be asked to attend such a school. I feel sure that much greater attention ought to be paid to the teaching of English composition, to English poetry and prose, and to English subjects generally. I also feel sure that much attention ought to be paid to natural science. And surely it can do no good for the classical masters to go on sneering at natural science subjects and calling them "stinks" as they do now.

I want, however, to speak more particularly of a much higher kind of school, which will educate the boy usually called clever and also the boy usually called stupid. As I have already remarked, I think that these names may sometimes be redistributed.

The school is one for boys from eleven to sixteen years of age. It ought in no way to be connected with any classical school. English subjects will predominate, but teaching in Latin and Greek and modern languages and other alternative subjects will be provided, although they will not be forced upon any boy. The masters who teach English ought to know enough Latin and Greek and Celtic and Old English and modern languages to be able to illustrate the derivation of English words through their roots. And they must be well read in English subjects and fond of English literature. They will make the boys fond of reading English, and encourage them to find out what they like best. Some boys will take to history and philosophy, some to poetry and imaginative literature. Every boy ought to get the best chance of developing his faculties. It may be asked —if we cannot make the average boy spend or waste twelve hours a week on Latin, what are we to do with him? At all events, now, we keep him doing something, even if it is only marking time. My answer is, you think only of his putting in time; well, then, let him put in his time at work that interests him; any work of that kind must be educative under an intelligent master who can help him in his studies if it induces him to look up information for himself. Thus, when reading travels or history, he will use the globe and raised maps and read geography, and hunt up plans of battlefields. Think of the things that a boy used to be punished for doing, and let him do those things under wise direction. I used to be punished for reading Scott and Cooper. Nowadays prizes are given to boys for their knowledge of Ivanhoe or Quentin Durward. Expand this into a system. A boy who loves to browse over Chambers's English literature ought to be guided in his browsing, and induced to take up something more than selections, and he may easily be induced to get off selections by heart if his teacher does not show his contempt by speaking of such exercises as *Rep.* (repetition).

Let the teacher take a leaf out of our methods of teaching chemistry and physics. It has been shown that twenty-five boys doing work in the laboratory during a lesson of an hour and a half or two hours can be managed by one teacher. Experimental lectures in a lecture-room have now been greatly discarded; such lessons as I speak of take place in the laboratory, but reliance is placed particularly upon the personal attention of the teacher being given to each group of students in charge of an investigation, the group not being usually greater than four in number, and often being less than two. These students are sometimes merely verifying or testing a statement made by the teacher or found in a book, but they are often finding out things for themselves. One idea underlying the work is that there ought to be more and more illustrations of simple fundamental principles. It is long before these simple things really become part of a boy's mental machinery; things like the mere definition of *force*, for example. It is, of course, quite different work for the teacher from anything that he used to have to do; for one thing, being much more exhausting. He cannot shirk his duties and sit down waiting for students to come to him. When teaching degenerates into mere maintenance of discipline, everything being regarded as right if the pupils are quiet and seem to be diligent, it is necessary to make a radical change, usually a dismissal of the teacher. It used to be that a science master gave an experimental lecture, and afterwards he had a very easy time, letting the students follow a set routine in the laboratory, but this will no longer do; such attendance at lectures and laboratory work means poor mental training.

Now, I would work out a system for English, English composition, English poetry and prose, geography, history, and other English subjects, on the lines that we have found so successful in natural science. An enormous change has been effected during the last fifteen years in the teaching of mathematics. The older methods always failed with the average boy or man. The new system, which is sometimes called *practical* mathematics, is based on the idea that students shall work experimentally, just as they do in their natural science. It is found that their eyes and faces are bright, they work hard, and they evidently enjoy their work. We have merely introduced common sense into the teaching; we have approached the student's mind from other points of view than the old academic one, from the only side on which he has ever been taught anything—the side of observation and trial. He weighs and measures. He does experimental geometry and mensuration, and is assisted by abstract reasoning just to the extent which interests him; he makes plans of the school buildings and maps of the district; algebra becomes interesting when in coordination with experiments in mechanics and physics; trigonometry becomes interesting in the actual measurements of heights and distances. The infinitesimal calculus is bound to be a weapon which any boy of fifteen easily gets to understand by actual use when he is dealing with dynamic experiments. In fact, the physical and mathematical laboratories

are in one, and the same teacher takes charge of both subjects and teaches them as much as possible together.

Furthermore, in the preparation of an account of an investigation there are practical lessons in English composition; there is sketching, and also more careful drawing with instruments, and the finding of empirical laws, using squared paper. In such a school every subject is being taught through all the other subjects; every boy is doing the work in which he is greatly interested, and no boy is attending merely and putting in time. Furthermore, out of school-time there might be the usual restrictions as to "bounds," but otherwise I would let a boy do pretty much as he pleased. "Prep." at boarding-schools and home lessons for boys at day schools are to be quite discredited. I would—it may cost a little more money—allow a boy to work in the workshops or laboratories or library or in his own room or common rooms at anything he pleases in this off-time, and I would give him advice only if he asks for it. If I saw a boy reading a penny dreadful I would not stop him; nor if he were reading Paine's "Age of Reason," or any wretched treatise on psychology or logic. I would in no way discourage a boy from acquiring a greater and greater fondness for reading, knowing that this is the foundation of future happiness and education, and that no harm which he can get from his reading is of the slightest importance in comparison with the importance of our main object. As he grows up he will become less and less fond of the sixpenny magazine. The school can at its best be merely a preparation for the lifelong education of the man. I would not keep the boy at school after sixteen. Let him then go into business, or to a science or technical school, or to the university.

Unfortunately for the present no university will take men without an entrance examination involving other languages than English. This is a great evil, but it is not going to last much longer. In the meantime a competent coach will prepare any student to pass the necessary examinations (say, in Latin and Greek) in three months, even if there is much other work to do. This is not a matter of learning any classics; it is rather the manufacture of some contempt for the classics, a necessary evil for the present. Indeed, for the present, but let us hope not for long, there are many other necessary evils. We have to find competent enthusiastic teachers, we have to persuade governing bodies to pay salaries two or more times as great as at present, we have to make parents see that some mental training and fondness for reading and writing are really of value, and that Tom Sawyerism is only childish.

The importance of primary education is now well recognised. Rich and aristocratic folk know that they are now in the hands of the common people in a democratic country, and it is important to see that the common people shall be made fit to rule and shall have a real sense of fairness and reasonableness. Above all, if they are to be good citizens we must cultivate their common sense. I think that in the schemes and the administration of primary education by the Boards of England and Scotland it is in a good way; but there is one great curse upon it, and the enormous sums of money spent upon it are greatly wasted. The local authorities give to every teacher far too much to do, and they give him only half his proper wages. In a few years the Government of our democratic country will be in the hands of the boys now at school. That they should be good citizens full of common sense is more important than any other thing. If they are without fondness for books, and if they cannot reason, their votes will be at the command of fraudulent or foolish, or perhaps only selfish or self-deceiving speakers. Our Empire was ruled by George III., and by God's grace we only lost America and piled up the National Debt; but think of an empire ruled by millions of Georges! Teaching the young requires great wisdom and sympathy, and we entrust it to people paid half wages, the "otherwise unemployed." In the secondary schools also we find this penny wise pound foolish policy, and it is particularly evil in the great technical schools. A city is proud of its magnificent college of science, first because of its architecture; secondly, because of its equipment in apparatus, perhaps in steam- and gas-engines and other expensive machinery. And the man in charge of the most important department of that college receives perhaps 250*l.* a year. He ought to get at least 600*l.* That is the market price of a fit man, and without a fit man the whole money and the time of students are being wasted; the thing is really a fraud, a whited sepulchre, and, of course, the principal is always a classical non-scientific man. Photographs of the building and its laboratories are very fine to look at in guide-books of the city, and the managers of the college get public thanks for their services. I know nearly all the technical and science colleges of Great Britain, and I scarcely ever see any of their complacent managers, members of their governing bodies, without wishing that I had some of the powers of the familiars of the old Spanish Inquisition. What right have they to undertake duties which require a knowledge of natural science?

The latest proposal of our callous copiers of the Germans is to make attendance at evening classes compulsory up to the age of seventeen. At present working boys attend evening classes voluntarily, although in many cases they are too tired to learn much. Yet many of them do learn. These boys are almost martyrs. They sacrifice so many of their poor pleasures, and indeed duties, that they certainly deserve success in life. But it is not fair to impose these sacrifices upon boys who are, as apprentices, learning the principles underlying their trade, and who are paid only small wages on the understanding that their masters teach these principles. In 1889 I introduced a Bill into the Kensington Parliament compelling employers to provide such instruction during the working hours. Reforms of all kinds proceed with exasperating slowness, but already many employers are carrying out this idea.

In some things we reformers have made way. It is now recognised almost everywhere that examinations ought to be conducted mainly by the teachers of a student. I have often put the matter in this way: Huxley used to teach about forty students in biology; we cannot imagine better teaching. But if those students had only wanted to pass the examination of London University it is quite certain that they would have done very much better by attending the class of a cheap crammer. A university consisting of two, three, or more federated colleges is very little better than a mere outside examining body, and this is what London University has always been. I am glad that a change towards something better is now about to take place. A number of separate universities would be better, but in two years or less, probably, the colleges of London will conduct their own intermediate and degree examinations. One result will be that when a man gets his degree he will not shut up his books for ever.

I would, however, point out that Old London University, which was a mere examining body, served an exceedingly important purpose. This statement may seem curious coming from a person who has always railed at London University as a mere examining

board. I still say that it was never a University at all in the past. But a man reading hard by himself, perhaps far away from a college, could have a severe test applied to his acquirements which encouraged him in his studies when he had no other encouragement, and the test was very rightly a severe test. To do away with its outside examinations altogether, as I believe is the intention of the authorities, will be exceedingly harmful. It would be impertinent in me to make a suggestion as to the distinction which might be made between a degree conferred by his own professors upon a man who has attended regularly a college of repute, and a degree conferred by a mere examining body upon an outside student. For the first, the examination test may be easy. The Oxford and Cambridge pass degree examinations are quite easy, and rightly so, for the real qualification is that an undergraduate shall have lived for three years in the intellectual and cultured life of an Oxford or Cambridge college. In the other case the mere examination is the only test, and it is rightly very severe. The two kinds of degree differ altogether in quality. In a new country of great distances I can imagine many good secondary schools to be established having neither sufficient funds nor sufficient pupils to be qualified as universities. Yet it may be of enormous importance that a few of the older pupils at such schools should as external students be examined for degrees by distant universities, which, in such a case, are merely outside examining bodies. I can see the gradual increase in importance of such secondary schools leading to the establishment of something higher—namely, colleges of university rank—and I can see such affiliated colleges becoming universities themselves perhaps after a period in which two or more of them federated themselves as universities. But I say that there ought always to be some examination machinery by which a student who is too poor or who through any other circumstance is unable to attend a university college may be encouraged to study by himself, by having his attainments tested.

In this address I have said nothing about the education of women. I have always advocated higher education for girls, but it is surely wicked to teach girls as if they were boys. Men are concentrative, and they specialise; women observe more and more about many things, and they really have more capacity for acquiring mental power. Until quite recently girls were saved from stupidity, but the high schools are now giving a crammed knowledge of facts and of the opinions of the tribe, so that girls and women are ceasing to think for themselves. The education of men is in a bad way, but that of women is becoming much worse.

I think that in this address I have put forward no idea that I have not already published time after time in the last thirty-five years. I put these views forward again because, after much thought and much experience, I still think them to be correct, and I feel sure that they must prevail. But I must confess that it is only a very hopeful man who can peg away at a thankless task as Dr. Armstrong and I have been doing so long.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Glasgow.—Dr. A. W. Stewart, lecturer in organic chemistry in the Queen's University of Belfast, and formerly lecturer in stereochemistry at University College, London, has been appointed lecturer in physical chemistry at the University of Glasgow, in succession to Prof. Soddy, now of Aberdeen.

By the will of the late Major-General Tweedie, his estate of Lettrick, in the parish of Dunscore, having an annual value of about 180*l.*, is bequeathed to the University of Edinburgh. The annual income is to be applied by the University to the establishment of scholarships for research into the early history, development, and religion of Eastern peoples; or in such way as may seem best suited to advance that branch of study.

The leading article of the August issue of the *Reading University College Review* deals with the teaching of applied science, and the question is considered from the point of view of chemistry. The writer urges that given a due knowledge of pure chemistry, all that is required for the mastery of any branch of applied chemistry is concentration on those analytical methods and physical problems which belong to it. Thus to succeed in any applied branch of the science a man must first be a pure chemist. He goes on to argue that the system of instruction in applied sciences followed in this country attempts too much and does too little. The syllabus should be restricted, while more time should be devoted to general principles. The applied part should not be taken separately, but should be interwoven with the rest and used to illustrate it. Speaking generally the student of applied science will profit most if his work in pure science is designed to give him adequate training in scientific method.

The calendar for 1914–15, that is, for the ninety-second session, of Birkbeck College, London, has been received. Full provision has been made for continuing the work of the college during the present academic year in the direction of supplying approved courses of instruction for degrees in arts, science, laws, and economics of the University of London, and offering other important educational facilities. The usefulness of the college is much curtailed by its limited accommodation: its pressing need is for increased space. More extensive college buildings, with additional class-rooms and larger laboratories better adapted to modern requirements, would give a great stimulus to the work of the college and add to its public utility. Attention is directed in an introduction to the calendar to the final report of the Royal Commission on University Education in London (1913), in which the Commissioners write (section 248): "We think that the original purpose of the founder of Birkbeck College and the excellent work that institution has done for the education of evening students who desire a university training, mark it out as the natural seat of the constituent college in the faculties of arts and science for evening and other part-time students."

A copy of the annual report, for the year ended March 31, 1914, of the Education Committee of the County Council of the West Riding of Yorkshire has been received. The report contains much evidence of sound progress during the year. The arrangements with the Universities of Leeds and Sheffield under which, in virtue of the general grants made by the County Council, certain definite work is undertaken by the universities and certain free places are reserved for nominees of the County Council, have been continued. In addition to external lectures on coal mining, given by the University of Sheffield, both Universities have been engaged also in the organisation and supervision of classes in coal mining, the Leeds University in the area of the West Yorkshire coalfield, the Sheffield University in the area of the South Yorkshire coalfield; and each university has made provision for the training in mine-gas testing, of persons selected by the committee as prospective teachers of this subject. The Joint Agricultural

Council of the three Ridings of Yorkshire has continued the work connected with education and instruction in agricultural subjects, acting through the agricultural department of Leeds University, on the same lines as before. Full particulars are given of the council's scheme of scholarships and exhibitions. This provides assistance for persons desirous of obtaining instruction in all grades of education other than elementary. It provides for the properly qualified pupil in the elementary school who desires to proceed to a secondary school and furnishes him at a later stage with the means to enter a university; it also offers instruction to boys and girls who have commenced work in office or mill and can devote only their evenings to the continuance of their education, as well as to the craftsman who desires to increase his usefulness by further study. For the benefit of artisans and workers in the leading industries of the West Riding, such as the textile trades, engineering, coal mining, and agriculture, a number of technological scholarships and exhibitions have been set apart to enable the holders to go through specialised courses, usually of two years' duration. Technological scholarships were held in 1913–14 by five engineers and five textile workers.

GERMANY'S AIMS AND AMBITIONS.

LORD ROSEBERY, on March 1, 1893, speaking at the Royal Colonial Institute, said: "We have to remember that it is part of our responsibility and heritage to take care that the world, so far as it can be moulded by us, should receive the Anglo-Saxon, and not another character." If we inquire what is conspicuous in the Anglo-Saxon character, most people will agree, I think, that it is based on regard for our neighbours' rights, a regard which has been the object of our laws and struggles for centuries. The Anglo-Saxon spirit is essentially one which makes for fair-dealing; the race has never been a race of oppressors. Equity, truth, and justice have been our watch-words; and on the whole the nation has acted up to its convictions. It is this national feeling which has led to our taking part in the present war; rather than see a treaty broken, rather than allow a small nation to be coerced into an immoral act by a large and powerful one, we have lent our aid to the French and the Russians, and we are all prepared to support to the death what we all believe to be a righteous cause.

The German view of a nation's duties is very different, and wholly irreconcilable with that of the British and Americans. In the first place, we regard the State as ourselves; we are the State. Representative government leads to this conclusion; if we do not like the policy of our representatives we can change them. But for the German race the State is an external, self-elected body, possessing absolute power over the lives of its subjects. It is for the State to determine what is best; with an army at its back it is useless to attempt to oppose its decisions. The essence of the Teutonic character is to compel everyone to obey what it conceives to be for the good of the community. While the Anglo-Saxon motto may be conceived as "live and let live," the Teutonic command is "live as the State would have you live."

The Anglo-Saxon ideal is the freedom of the individual; the Teutonic ideal the compulsion of the individual by an omnipotent oligarchy.

The effect of the applications of science to practical ends has, during the past century, been the great prosperity of the civilised world. The standard of living has been immensely improved; disease has been diminished, and the average duration of life has been much prolonged. Moreover, the use of machinery has greatly economised energy; the effective production of the race has enormously increased. As a concomitant, the density of the population in European, and indeed in all countries, has also increased, and ever in increasing ratio. It is obvious that such increase cannot go on indefinitely; up to now the accumulation of population has to some extent been modified by emigration; but here, again, there must be a limit. That limit, however, is still a distant one for England; her colonies are still capable of absorbing an enormous population. This is doubtless the reason why British statesmen have practically left unconsidered the economic problem of the increase of population beyond the possibility of feeding it. Moreover, it is not the Anglo-Saxon spirit to prepare to face future difficulties; each difficulty is grappled with when it arises. Not merely is this the character of our race, but our democratic government renders any other course of action practically impossible.

German, or, to be more accurate, Prussian statesmen, have foreseen that difficulties will arise, owing to the natural increase of the German people. Her colonies are relatively unimportant; moreover, they are badly administered, and do not attract settlers. It is true that enormous numbers of Germans have emigrated; it is said that there are no fewer than a million Germans in Brazil; and a very much larger number has found a home in the United States. But these are no longer under German rule; they regard themselves as emancipated, and soon lose connection with, and affection for, their native land. This is naturally repugnant to the Prussian ruling class; and their remedy is war.

The doctrines of humanity are deeply rooted in the Anglo-Saxon spirit; lives are preserved which do not represent a high standard of health and strength; and what may be termed the "virility" of the population decreases. Again, our legislators, though aware of this fact, have taken few steps to face it, if indeed any practical steps are possible. German statesmen, on the other hand, have attempted, by the physical training inseparable from universal military service, to improve the condition of the partially unfit. They imagine that they have secured an advantage over other nations by doing so; and their ideal, with which they have infected practically all Germans, is to secure world supremacy for their race, in the conviction that the condition of humanity will thus be ameliorated. This is the aim which has permeated all classes

of German society during the past generation; this is the cause of the present war. No means are to be neglected to secure this end; righteousness, truth, and justice are to be sacrificed in order that the German race may persist. The German nation has been educated to believe in this ideal by the Prussian ruling caste: "Deutschland über Alles in der Welt." Therefore the war.

Now it may be pointed out that the youth and early manhood of the race are the fighting class; and that by war the most able-bodied of the population are, at least partially, eliminated, with the inevitable result of the deterioration of the race as a whole. Probably it would be argued by Prussian statesmen that the relative number of deaths in war is small; and a successful war will leave abundant healthy men to perpetuate the race. Deterioration by the effects of war, they may contend, is not so wide-spreading as deterioration by the saving of lives of little value.

I have tried to state the case for the German nation; it represents an attempt to aid the elimination of the unfit, the unfit being all who do not hold with German ideals.

Now a race with such an ideal becomes impossible. It cannot be denied that Germany has contributed much in the past to literature, to science, and to the art of music. Individual Germans have attained the highest eminence, and have gained universal admiration. But the originality of the German race has never, in spite of certain brilliant exceptions, been their characteristic; their *métier* has been rather the exploitation of the inventions and discoveries of others; and in this they are conspicuous. The same obedience to command and the same attention to detail may be noticed in their industrial and scientific work as in their army. And of recent years, according to common report, commercial morality among the Germans has been at a low ebb. They are disliked as business men; their methods are not regarded as fair, or their word as trustworthy. Even in the world of science this spirit is by no means unknown. In spite of their boasted progress in what they imagine to be civilisation, they have been relapsing into barbarism. And the execrable deeds of their army—murder of defenceless non-combatants, destruction of priceless buildings, heartless cruelty to women and children—all these are merely the outward and visible sign of their spiritual beliefs. The aim of science is the acquisition of knowledge of the unknown; the aim of applied science, the bettering of the lot of the human race. German ideals are infinitely far removed from the conception of the true man of science; and the methods by which they propose to secure what they regard as the good of humanity are, to all right-thinking men, repugnant. These views are not confined to the Prussian ruling caste, although in it they find active expression: they are the soul of the people.

The conclusion is that this war is a war of humanity against inhumanity; of principle against expediency; of right against wrong. Fortunately, the present aspect of the war is favourable to the Allies; and justice and mercy will undoubtedly triumph.

What is to be justice and mercy? First and foremost, reparation must be made to the Belgians for the outrages which they have suffered; next, France must claim not only damages for the present invasion, but for the indignities of 1871; Russia and Great Britain will no doubt demand compensation. The motto of the Allies must be "Never again." Not merely must the dangerous and insufferable despotism which has eaten like a cancer into the morals of the German nation be annihilated, but all possibility of its resuscitation must be made hopeless. The nation, in the elegant words of one of its distinguished representatives, must be "bled white."

Will the progress of science be thereby retarded? I think not. The greatest advances in scientific thought have not been made by members of the German race; nor have the earlier applications of science had Germany for their origin. So far as we can see at present, the restriction of the Teutons will relieve the world from a deluge of mediocrity. Much of their previous reputation has been due to Hebrews resident among them; and we may safely trust that race to persist in vitality and intellectual activity.

It would be unworthy of the dignity of scientific men to imitate the example of some of the German professors in "abandoning the distinctions conferred on them by English learned societies." It must be remembered that the award of distinctions to Englishmen has been the act of the older race of German men of science, who form the councils of the various academies. Doubtless these men deplore the degradation of their race, as manifested in the outburst of barbarism which has shocked the feelings of the whole world, and it would be a graceful act if English men of science were to retain the marks of their appreciation.

In conclusion, it cannot be contended that the present war has in any sense been promoted by

the imagined spread of education and science in Germany. It affords to all men a lesson, however, that the moral sense of a nation requires educating, as well as the intellect; that a regard for truth, and for the sanctity of a promise are more important possessions than a knowledge of recent discoveries and inventions; and that the intellectual progress of a country is to be measured by the intelligent participation of every citizen in problems of government and of advance in the moral and mental conditions of the race. The splendid response to Lord Kitchener's call to arms shows that, in spite of many small and annoying eddies in the stream of British life and thought, it still flows steadily in the good old channel of probity and honesty.

WILLIAM RAMSAY.

THE GEOGRAPHY OF THE BRITISH EMPIRE.

The Oxford Survey of the British Empire. Edited by Prof. A. J. Herbertson and O. J. R. Howarth.

The British Isles, and Mediterranean Possessions (Gibraltar, Malta, Cyprus). Pp. xii + 596 + 7 maps.

Asia, including the Indian Empire and Dependencies, Ceylon, British Malaya, and Far Eastern Possessions. Pp. x + 505 + 5 maps.

Africa. Pp. xvi + 547 + 5 maps.

America. Pp. x + 511 + 6 maps.

Australasia. Pp. xii + 584.

General Survey. Pp. viii + 386 + 1 map. (Oxford: Clarendon Press, 1914.) Price 14*s.* net each.

THOUGH arranged as a series, these volumes can, it would appear, be bought separately. Each volume has the same preface, and the order in the series is distinguished on the back by stars instead of numbers, so as to conceal the oddness of an odd volume. Each volume is by several authors, who have obviously, each as an expert in his own branch, been left a good deal to themselves as to the manner in which their own subjects are to be treated. Each volume is provided with an index, with coloured folding maps showing the physical features, geology, or political divisions of the regions dealt with, with text-maps and diagrams, largely climatological, in black and white, to illustrate the same or other things, and with plates giving illustrations of typical scenery. Each volume, too, has at the end another useful feature, a set of statistical tables, or tables and diagrams relating to the dominions dealt with in the volume, those in the last volume being of a more general and comprehensive character. All the volumes except the last, moreover, have a short gazetteer or alphabetical list of the more important places mentioned in the corresponding volume, with a statement of the situation, and notes as to points of interest. This arrangement will obviously facilitate the bringing up to date of later editions.

The editors are to be congratulated on the success with which the whole work has been carried out. They have obtained the services of a large number of highly competent men, and all those interested in the Empire will feel that they owe them a debt of thanks for the mass of trustworthy information that has here been accumulated, and the instructive statement and discussion of problems connected with the Empire as a whole or its different parts.

In the treatment of each of the larger Dominions there is the same general arrangement of topics, but there is no pedantic adherence to the same grouping of these under chapters. It would have been worse than pedantic to have exactly corresponding chapters in dealing with units so diverse as the British Isles, India, and the Dominion of Canada. In the treatment of the British Isles common sense required that there should be much more detail than could be spared for any other part of the Empire. There are thus five or six chapters under different headings in the section on the British Isles, which occupies, if we include the islands in the British seas, more than five-sixths of the first volume, devoted to the topics which in the section on Canada are treated by Prof. Mavor, of Toronto, in three chapters of remarkable excellence under the general heading "Economic Survey."

We have said that the different authors have evidently been left much to themselves in the treatment of the subjects allotted to them. Inevitably this leads to a certain amount of repetition and overlapping, occasionally to the expression of divergent views. Thus it is natural to find Mr. R. D. Oldham, who deals with the physical geography of India, and Mr. J. S. Cotton, editor of the "Imperial Gazetteer of India," who handles Indian agriculture, both take up the subject of Indian soils, and it is distinctly instructive to find that the man of letters is quite confident as to the origin of those soils, while the geologist is not. On matters of more importance such discrepancies are not at all to be regretted. They keep the student in mind of the fact that there are multitudes of questions on which competent authorities trained to inquire into truth for its own sake hold different opinions. Even where there is no actual conflict of opinion it is useful to have different shades of view expressed. Those,

for example, who read in the Africa volume Mr. Basil Worsfold's interesting and valuable statement of native problems in South Africa will be able to read them in the light of the observations made by Mr. E. B. Sargant in the chapter on educational problems of the Empire, culminating in the reflection that where there are two distinct social orders, of which one represents largely the hewers of wood and drawers of water, "any neglect of the development of the more backward, group must react unfavourably upon the development of the other, and ultimately leave its mark upon the whole Empire" (General Survey, p. 233), as, on the other hand, those who read these highly general observations will have the advantage of considering them in the light of the more concrete presentments of fact elsewhere.

While there is so much to be thankful for in these volumes there are nevertheless one or two things to regret. To begin with a minor matter, it may be pointed out that some of the maps and diagrams are not so completely self-explanatory as one would like them to be. Thus, in the map of the "Economic Regions of Canada" in the America volume, it is not clear what territory the so-called "Central Agricultural Region" is intended to include. In the map of the "Railways of Eastern Canada," p. 189, there seems to be some mistake in the reference. In the very interesting rainfall diagram on p. 334, as on that of the monthly discharge of the Nile on p. 345, it would be well to add at least the latitudes of the places mentioned. In the former, for example, the contrast between Wadelai and Ghaba Shambe would be all the more striking if we knew that there there is only 4° of latitude between the two places, a fact which there is no means of finding out from the book, inasmuch as Ghaba Shambe is not named on the map of north-east Africa, between pp. 316 and 377.

Then, further, it is both surprising and regrettable that in a work coming out virtually under the auspices of the Oxford School of Geography there should have been apparently so little systematic endeavour to give prominence to geographical influences. Even in the section on the British Isles, a good deal more space is given to the administration of towns than to the conditions that tend to fix their sites and promote their growth. In the Australasia volume there is indeed a deliberate effort to develop those influences in the chapter on physical geography, but this attempt, to our mind, suffers somewhat from the prominence given to geological history in setting forth those influences. The sentences in this chapter may in many cases be individually interesting, but the reading of a paragraph, notwithstanding the illustration by block diagrams, is often hard, that of a sequence of paragraphs still more so.

But there is one chapter conspicuously free from this fault, a chapter by an unnamed writer in which what may be called the geography of British policy and of British strategy is expounded in such illuminating fashion that the most ignorant under this head will be enlightened, a chapter which will be read in present circumstances with the keenest interest, and for the sake of which alone it would be worth while for anyone who has fourteen shillings to spare to buy the volume—that containing the general survey, an admirable volume in other respects. We may conclude this review with a quotation from the chapter (p. 190), which all of us may ponder with profit at the present time:—

"The geographical situation of the British Isles confers certain advantages from the point of view of waging offensive warfare. It greatly facilitates the protection of our oversea trade against an enemy that is compelled to issue from the North Sea to gain access to the Atlantic, and it enables us to keep the ports on the other side of the Channel under effective observation should necessity to do so arise. But against those advantages must be weighed those conferred by a possible enemy for waging warfare by the double exit from the Baltic *viâ* the Kiel Canal and the Skaggerak. This double exit not only increases the difficulty of maintaining effective observation on any hostile fleet that can make use of either passage, but imposes upon us the necessity of keeping our main fleet in a position from which it can ensure bringing the enemy to action before he can break out of the North Sea, and in certain circumstances might prevent any division of the battle fleet."

G. G. C.

POPULAR NATURAL HISTORY.

(1) *The Courtship of Animals.* By W. P. Pycraft. Pp. xvi + 318 + 40 plates. (London: Hutchinson and Co., 1913.) Price 6*s.* net.

(2) *Hunting the Elephant in Africa and other Recollections of Thirteen Years' Wanderings.* By Captain C. H. Stigand. With an Introduction by Colonel Theodore Roosevelt. Pp. xv + 379 + plates. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 10*s.* 6*d.* net.

(8) *Common British Moths.* By A. M. Stewart. Pp. viii + 88 + 15 plates. (London: A. and C. Black, 1913.) Price 1*s*. 6*d*. net.

(1) MR. PYCRAFT has written a very interesting comparative study of the love-making of a great range of animals selected from most of the main zoological groups. The explanation given by Darwin as to the origin of the secondary sexual characters is now, he answers, rather out of date, and Wallace's "arguments for sexual selection are far from convincing and often inconsistent." The "theme" of the book is to show that a sharp line must be drawn between those attributes which are necessary to achieve individual survival and those to achieve the survival of the race-factors which, in the latter, are embraced under sexual selection. Much, Mr. Pycraft believes, hitherto attributed to the action of sexual selection alone—such as the behaviour of animals during sexual activity and the colours they display at this season—is largely governed by the action of "hormones" (the secretions of various ductless glands in the body). "Suggestion" is also necessary, but "suggestion does not suggest" till the hormones have rendered the system inflammable; "suggestion by display" of some kind, as an aphrodisiac, is a necessity, or "how else can desire be indicated? Here is sexual selection." The limits of space assigned to us forbid our discussing this question—which is very interesting, but perhaps less entirely novel than the author realises—beyond mildly "suggesting" that Mr. Pycraft's system seems so saturated by one or more hormones as to "exalt" his particular point of view somewhat at the expense of others. We heartily recommend the book, nevertheless. It contains eighty illustrations on art paper.

(2) Captain Stigand is a well-known African official, devoted to hunting, who always provides his readers with an entertaining, well-written story. The unending stream of books on big-game hunting has, however, now made us fairly intimately acquainted with the lives and artifices of both the hunter and the hunted, so that from this point of view the author's elephant-hunting episodes are less interesting to the general student of nature than the discussion we have in his book upon protective coloration applied to big game. Mr. Roosevelt, in a foreword to the volume, avers, in his usual strenuous language, that the extreme theories of Poulton and Thayer "on this subject" have no bases whatever "in fact," and Mr. Wallace has "strained the recognition-mark theory to an impossible point," but that Captain Stigand's observations now leave "no excuse for further mistakes in the matter." But for the editorial fiat as to space, we are of opinion that it might still be shown that "all is not yet up" with the earlier theories. We can only refer those interested in the subject to the book, to wrestle out the matter for themselves.

(3) Mrs. C. Villiers Stuart's pages form charming memorials of the wonderful old, beflowered, and be-avenued gardens of the Indian emperors, with their warbling fountains and their running waters, so delicious to eye and ear in a parched land. She describes them not only in choice and delicate language, but depicts them in water-colours of great beauty and charm. One of the author's objects, apparently, in writing this book has been to give expression to the hope that in the New Delhi similar gardens may be reproduced. This is a delightful vision; but we greatly fear that the romance that haloes the Mughals and the beauties of their harems, of whom these walled pleasaunces were the shady ambulatory, cannot be revived in our days, and be the gardens of New Delhi never so gay and be-fountained, they will never reproduce those delightful enclosures as they appear to us through the sunlit haze of four hundred years.

(4) We have found the little book by M. Paul Noël, director of the Laboratory of Agricultural Entomology of the Seine-Inférieure, with the quaint title of "Ce que j'ai vu chez les bêtes," very delightful reading. It is written in the very simple, elegant, but exact language for which French scientific writers are so distinguished, and deals with a large number of the common insects, birds, reptiles, and mammals of the country. The author describes and figures several very admirable automatic appliances—for catching insects, rearing larvæ, and other purposes—invented by him in the course of his experiments and observations. Had it not a better use, it would form a very excellent French primer for young nature students.

(5) Mr. F. Duncan's book may be called a digest of the several volumes of the well-known "Cassell's Natural History," by the late Dr. P. Martin Duncan, although to attempt to deal adequately with the whole animal kingdom, as is done here, in a comparatively small volume, is,

we think, an over-bold adventure. The space allotted to many of the phyla is disproportionate to their importance. It is somewhat difficult to form an opinion of the class of reader for whom this book is intended, for we think that neither the general reader interested in natural history, nor the serious zoologist in need of a book of reference, will find it very satisfactory. The volume is well illustrated by 200 photographic reproductions.

(6) Mr. Lucas, the director of the American Museum of Natural History in New York, gives in this volume an account of a number of the most striking prehistoric animals on view in that institution, to the library of handbooks of which it forms a valuable addition. The author's name is sufficient guarantee for the accuracy of its contents; and Mr. Knight's—an artist well known for his skill in depicting prehistoric animals—for the restorations provided in it. Biographical references are appended to each chapter, and there is a sufficient index.

(7) This is a posthumous volume by Mr. W. F. Kirby, well known by his entomological work. As a general account of the lepidoptera the volume will be found accurate, and written in a more than usually interesting style. It is well illustrated by twenty-eight very excellent coloured plates, "made in Germany."

The last volume (8) on our list, one of the "Peeps at Nature" series, dealing only with our common British moths, is more sketchy than Mr. Kirby's. The colour photographs with which it is illustrated are, however, specially good.

ELECTRICAL ENGINEERING.

(1) *Telegraphy.* By the late Sir W. H. Preece and Sir J. Sivewright. Revised and partly re-written by W. L. Preece. Pp. x+422. (London: Longmans, Green and Co., 1914.) Price 7*s.* 6*d.* net.

(2) *Continuous and Alternating Current Machinery.* An Elementary Text-book for use in Technical Schools. By Prof. J. H. Morecroft. Pp. ix+466. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 7*s.* 6*d.* net.

(3) *Laboratory Manual, Direct and Alternating Current.* Prepared to accompany Timbie's "Elements of Electricity." By C. E. Clewell. Pp. vii+100. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 4*s.* 6*d.* net.

(6) *Incandescent Electric Lamps and Their Application.* By Daniel H. Ogley. Pp. x+107. (London: Longmans, Green and Co., 1914.) Price 2*s.* 6*d.* net.

(1) A BOOK based on the immense experience of the late Sir Wm. Preece could scarcely fail to be of the greatest value to telegraphists at large; when, in addition, it has passed through edition after edition for nearly forty years, it is almost superfluous for a reviewer to give either praise or blame. The present edition has been again revised and brought up to date; it has been recast into a larger size of page, which we consider an improvement.

For those who are now beginning their subject we would say that the work aims at describing the simpler methods of land telegraphy, and includes the principles of duplex, quadruplex, and multiplex working, besides the elements of telephone exchange system. There are thoroughly practical chapters on materials and outdoor construction, besides information as to faults and tests. With scarcely an exception, the descriptions are lucid and clear; the literary style is pleasing, padding is absent, and practice lives on every page.

Submarine telegraphy is not included, being regarded as beyond the range of the book. We think it would have been well if wireless had been treated in the same way, as the chapter on this subject (the last one) does not give the reader the same grasp of essentials that the remainder of the book does.

(2) After a careful study of this excellent text-book, any intelligent engineer or engineering student ought to have a good general knowledge of the various kinds of electrical machinery now in use. Although the treatment is of an elementary kind and includes very few formulas, it is very thorough. It discusses all the essential actions in the more important machines very clearly, and includes many useful points which are seldom to be found in text-books. It is somewhat unfortunate that in the preliminary discussions given in the first few chapters the author has chosen entirely to ignore certain facts, and so gives the student a false impression, which he has to correct when the full discussion is reached later on. Thus, the reader to whom the matter is new would probably gather from p. 20 that magnetic hysteresis is the only source of loss in

an armature core; from p. 81 that the correct position for the brushes never depends on the load; and from p. 85 that the heating of a continuous-current armature is the only thing which limits its output.

The book is well illustrated, both by diagrams and half-tone blocks. The latter have mostly been derived from the literature of the large American manufacturing companies, but they have been well chosen; in a few cases only, mostly of instruments, do they show too little detail for the purpose in view. The British reader must, of course, remember that the book is American, and that the statements as to standards and regulations do not necessarily apply to this country.

(3) This book appears to be specially written for use in the author's own laboratory, and we scarcely think it will be of much service elsewhere. It deals with twenty experiments on continuous-current machines and apparatus, and ten on alternating-current ones. It can scarcely be said to describe them, and it certainly does not give those useful practical hints which every laboratory instructor knows to be necessary to enable even the best students to carry out their work successfully. The student is referred to another book for practically everything in the way of information; as we have not seen that book, perhaps it would not be quite fair to criticise this one in detail. But we must confess that except in special circumstances we should never think of using 110-volt mains for measuring the resistance of a yard or two of wire or of the armature of a dynamo, nor of complicating matters by the addition of a short-circuiting switch for every ammeter. On the other hand, we should certainly specify the use of fuses to guard against accident, although the author omits them from his diagrams and instructions.

(4) This excellent little book is a collection of formulas for calculating the voltages and currents at any point in a power transmission line the loads and constants of which are known. It is more a reference book for engineers who have to make such calculations than a text-book for students, but to those of the latter who wish to get up this particular work we can highly commend it. Following an ingenious chart from which the desired results can be read off with sufficient accuracy in the case of short lines, we are given, in tabular form, sets of formulas of increasing degree of accuracy to suit the chief cases which arise. The limits of application are carefully indicated in each case.

Part ii. gives an account of the theory on which these formulas are based; this portion is a model of conciseness combined with lucidity. Part iii. is a repetition of the tables of formulas, with the addition of tables of constants of copper and aluminium cables for the American standard frequencies of 25 and 60 cycles per sec.

(5) This book is non-mathematical and can be thoroughly recommended to those for whom it was written. It gives a very good account of the Marconi system, and also of the various other ones about which the public have lately heard so much. With few exceptions, the descriptions are good and the illustrations are excellent. We should have liked a rather better elementary account of the production of oscillations and of the emission of waves from the oscillator, and also a more convincing explanation of the action of the Marconi magnetic detector. Nor can we imagine any reason for the peculiar connections given on p. 50 for a shunt-wound motor starter.

(6) We wish we could compel all architects, wiring contractors, shopkeepers, and users of electric light generally to read this little book. We might then have fewer glaring (in more ways than one) examples of how not to arrange artificial illumination. The book contains little about the construction of the lamps, but gives an excellent account of their characteristics and of the principles which must be followed if a pleasing result is to be obtained from their use.

DAVID ROBERTSON.

CELESTIAL MECHANICS.

An Introduction to Celestial Mechanics. Second revised edition. By Prof. F. R. Moulton. Pp. xvi+437. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) Price 15*s*. net.

THE appearance of Prof. Moulton's introductory treatise on dynamical astronomy in a second edition is a sufficient proof that the work, which was first published twelve years ago, has satisfied a certain demand. This is very natural, for there is no similar book which covers the same ground. After the revision which it has now undergone it should prove even more useful than in its original form. The author's aim has been to give the student that general view of the whole subject, so far as it can be treated by fairly elementary methods, from which he may pass on, if he pleases to go further, to the technical details which are to be found in treatises on "Bahnbestimmung," or to the refined mathematical processes which are developed in theoretical works on celestial mechanics, or in the original memoirs of the great masters.

The early chapters develop the problem of two bodies in undisturbed motion. They lead up

naturally to the problem of determining orbits, which has received a new and admirably clear treatment, and is now placed in its logical order as an illustration of the application of the preceding theory. Even so, the fourth chapter, which deals with attractions, seems to some extent out of place, as it interrupts the study of those parts of the subject which depend essentially on particle dynamics. An interesting chapter on the problem of three bodies leads up to the final section of the book, in which the subject of perturbations is discussed both geometrically and analytically. These two methods will scarcely appeal with equal force to the same class of student.

The book is probably better adapted to the requirements of the American than of the English student. In this country it would be assumed that a reader who was capable of really profiting by the last chapter, for example, must have a considerable mathematical equipment. One would therefore expect a more thorough treatment of some points for which room might be found by omitting some of the more elementary explanations. In America, on the other hand, there is more chance of appealing to some immature but keen student who will be induced to pursue his studies further.

Numerous examples are given, and an index. An excellent feature is to be remarked in the historical and bibliographical notes. With the dictum that Galileo was a man of greater genius than Kepler we are tempted to disagree profoundly; but when genius runs in such distinct moulds, who is to decide? H. C. P.

OUR BOOKSHELF.

The Practice of Navigation and Nautical Astronomy. By Lieut. H. Raper. Twentieth edition. Pp. xxv+934. (London: J. D. Potter, 1914.) n.p.

IT is possible to keep the most valuable educational treatise too long before the public; methods grow obsolete with lapse of time and in altered conditions, but later editors, fettered by the spell of tradition, fail to use the pruning knife with sufficient freedom. As a pioneer instructor, seventy-five years ago, Raper's work was admirable. He raised the standard of accuracy, he appreciated the necessity of systematising processes, of shortening calculations, and of ensuring correctness in working. Others occupying the more advanced outposts that he made tenable have improved on his methods, benefited by wider experience, and have aimed at greater efficiency. Of course there is nothing wrong in Raper's book; too many critical eyes have examined its principles, and too many practical hands have tested its usefulness. But accuracy of statement is not all we look for in modern treatises. We expect to find placed at the service of the student all that has been achieved by science, analytical or practical.

Tested by such criteria, the treatise that guided admirably the navigators before the age of steam or of iron and steel built vessels is a little disappointing. In a modern book one would scarcely expect the explanation of Sumner's method of finding a ship's position at sea tucked away in an appendix or limited to a few paragraphs in the text. So far as we can see the student would not suspect that the time-honoured noon sight for latitude, and the morning or afternoon sight for longitude, are but special cases of this most powerful method. The theory of the Sumner Lines of position is so easy to understand, and at the same time is so widely applicable, that it should be made the basis upon which the whole theory of practical navigation depends. Again there is no mention of the desirability of observing time signals sent out by wireless telegraphy, and of the opportunities thus afforded for obtaining accurate Greenwich time. The practical methods suggested by Darwin for deriving improved tidal tables receive but the scantiest mention. These may be slight defects, but we think they indicate the inadvisability of attempting to accommodate an excellent book in its day to the requirements of another generation, possessing enlarged facilities and seeking more scientific instruction.

W. E. P.

Memorabilia Mathematica, or the Philomath's Quotation Book. By Prof. R. E. Moritz. Pp. vii+410. (New York: The Macmillan Co., 1914.) Price 12s. 6d. net.

PROF. MORITZ has brought together more than two thousand passages from the writings of mathematicians, philosophers, and others, and has grouped them under twenty heads, as well as indexed them under nearly seven hundred topics. Among the subjects of the groups of passages which make up the chapters of the book are:—the object, nature, value, and teaching of mathematics; study and research; persons and anecdotes; logic, philosophy, and science in relation to mathematics; arithmetic; algebra; geometry; the calculus and allied topics; concepts of time and space; paradoxes and curiosities. All the passages are in English, having been translated when the original extracts were in other languages. Full references are given, so that the originals can be consulted by the inquiring student when desired.

The preparation of such an extensive collection of notable utterances of some of the world's greatest thinkers must have involved enormous labour; and many writers and teachers will be grateful to the author for providing them with this anthology of mathematical philosophy. The extracts are of varying length and merit, but they are all interesting, and the grouping, as well as the index, enable selections upon particular aspects of mathe-

matical thought and work to be found easily. Passages 907 and 1643, which are given in German from Schiller and Jacobi, as well as in English, appear to be repetitions of the same story in slightly different renderings.

Zur Lehre von den Zuständen der Materie. By Prof. P. P. von Weimarn. Band I.: Text. Pp. x+190. Band II.: Atlas. Tafeln lii. 2 Vols. (Dresden and Leipzig: T. Steinkopff, 1914.) Price 7 marks.

THESE two volumes are put forward in proof of the author's main thesis "that colloid-amorphous properties appear in bodies as their comminution increases, and that such comminution is possible in all bodies." The well-executed atlas of plates reproduces photographs of crystallisation processes in various concentrations, chiefly of barium sulphate and aluminium hydroxide. It is shown that the size of the crystals is strongly influenced either way by the concentration. Examined in the ultra-microscope, jellies and transparent colloid structures generally show minute particles which are essentially crystalline, differing from crystals only in their size. Any solid, sufficiently comminuted, might be made into a "solid mist" of particles showing Brownian motions, but the latter are just what leads as a rule to crystalline agglomeration. By comminuting aniline-blue into a neutral substance (urea), Pihlblad obtained colloid solutions of the former in water of any degree of fineness. The author, in view of these facts, proposes to substitute the term "dispersoid" for the less significant term "colloid," and would call the science of colloids "dispersoidology."

PROBLEMS OF THE PENGUINERY.[1]

DR. LEVICK has made a fascinating study of the Adélie penguins (*Pygoscelis adeliae*), and the charm of his book is enhanced by his beautiful and really interesting photographs. He has certainly a good subject, for penguins are among the quaintest of living creatures, among the most ancient of birds, triumphs of adaptation to aquatic life, remarkably congruent with Antarctic conditions, and very instructive from a psychological and even sociological point of view. Inquisitive, unafraid, altruistic and social, they make a strong claim on our interest and sympathy.

The Adélie penguins spend their summer and bring forth their young in the far South. They seek out wind-swept places, kept bare of snow, where they find solid ground and pebbles for making nests. After the chicks have been sufficiently educated to be able to fend for themselves, young and old leave the southern limits of the sea and make their way to the pack-ice out to the northward. The first year's birds remain on the pack for two winters, until they get their adult plumage. "The spring following this, and probably every spring for the rest of their lives, they return south to breed, performing their journey, very often, not only by water, but on foot across many miles of frozen sea." That they find the breeding ground is remarkable, for they cannot see far when they are swimming (and there is often nothing to be seen), or when they are "tobogganing," and their horizon when walking

"Occasionally an unaccountable 'broodiness' seemed to take possession of the Penguins." From "Antarctic Penguins."

[1] "Antarctic Penguins." By Dr. G. Murray Levick. Pp. x+140+ plates. (London: W. Heinemann, 1914.) Price 6s. net.

is only one mile distant. Dr. Levick believes that they have a special sense of direction.

At Cape Adare the penguins returned from the sea about the middle of October; they were at first fatigued and sleepy but soon began to pair and nest. Dr. Levick describes the combats of the cocks, who strike one another doughtily (with one flipper at a time, but ambidextrously); the gentleness and patience of the combatants in their overtures to their desired mates, who make some show of reluctance and have a tendency to hen-peck; the ecstatic attitude assumed at times by either sex, with an associated *chant de satisfaction* which seems to arouse the other partner to come to soothe the first; the activity of the cocks in gathering stones for the nest, often stealing them (a preference for bright colours was noticed); and the individual differences in character, for there are vigilant and unwary, tough and timorous birds. A very remarkable fact is that they do not eat anything all the time!

The fast may be prolonged for twenty-seven days of strenuous life. Thirst is quenched with snow, and on rare occasions the cock may bring a lump to the nesting hen. Incubation seems to last for rather more than a month, the female taking the first fortnight while the male goes off to recuperate; towards the end of the period the parent birds go to the sea in turn, feeding greedily on the abundant Euphausid crustaceans. The developing eggs have to be protected from the cold and from the intrusive skuas. "Evidence goes to show that the sea-leopard is the only living enemy, excepting man, that threatens the life of the adult Adélie penguin." Dr. Levick gives a delightful account of the habits of the penguins in the water and of their games. But there are two points of even greater interest. As the chicks become bigger and their appetites likewise, the turn-about method of securing food is inadequate. "The individual care of the chicks by their parents is abandoned, and in place of this colonies start to 'pool' their offspring, which are herded together into clumps or *crèches*, each of which is guarded by a few old birds, the rest being free to go and forage." The guardians of the *crèche* protect the chicks from the skuas and from the not less troublesome "hooligan" cocks (apparently idle bachelors and wicked widowers). Also suggestive of social development was an extraordinary occurrence witnessed by Dr. Levick and Mr. Priestley, a congregating of penguins into massed bands some thousands strong and an apparent drilling! From one of the motionless bands a single bird ran out in the direction of another band, and stopped. In a flash the entire band from which he came executed the movement "left turn." The band which he had approached did the same, and the two bands marched straight towards one another, and joined to form one body. Similar procedure continued for many hours. Dr. Levick's suggestion is that the "drilling" is a reminiscence of "massing" before migration, going back perhaps to flying days! We have to congratulate the author on his well-told story.

THE PROTECTIVE TREATMENT AGAINST TYPHOID FEVER.

Typhoid fever is inseparable from war. It finds in war, ready for it, all that it could desire. In times of peace we have a thousand ways of avoiding it, a thousand ways of holding it up: so sure are our defences, so elaborate our plans, that we get into a stupid way of thinking of typhoid fever as if it were due only to "insanitary surroundings"; as if it were a disease altogether unlikely to show itself within ten miles of a good medical health officer. Then comes war; and, with declaration of war, comes the general mobilisation of the infective diseases. They are called up, they are sent to the front. Louvain as it was and Louvain as it is are scarcely more unlike than are typhoid in times of peace and typhoid in time of war.

For sheer inaccuracy it would be difficult to surpass a paragraph lately published in a little journal which bears a medical name, but certainly does not in this matter represent either medical opinion or public opinion. This journal "objects *in toto* to serum inoculation as a method of dealing with typhoid." We can measure the wisdom of the little journal, here, by the fact that the protective treatment against typhoid is not a serum-treatment, and has nothing to do with any sort or kind of serum. Then the journal says: "In the parts of France where our troops are operating there should be no difficulty with regard to hygiene. The troops are not shut up in a city closely invested and living on famine rations, but are constantly on the move in a land flowing 'with milk and honey,' not to mention rivers of grape juice, which is, if rationally used, Nature's own 'anti-typhoid serum.'" It says that; it really does. And one of the "anti-vivisection" societies has published an advertisement saying that the protective treatment "leads to tuberculosis"!

Typhoid is, of course, already taking part in the present war. Given the Allied Armies and the German Army in the Western Theatre, how should there not be typhoid? The only question is, How much more will there be a month hence? The lateness of the year, happily, will kill off flies, which are great carriers of the disease; but the flies are not yet gone, and they will more or less repeat that deadly part which they took in the South African War. There is plenty of the disease for them to carry. "It is well known," says Sir Almroth Wright, in the *Times*, September 28, "that the infection of typhoid is thickly sown all along the frontier of France and Germany." Besides, among two millions of men, there are bound to be some who have the germs of the disease in them. And what is the good of talking of "sanitation," as if our men could have the warm baths and the water-closets of the average Englishman's home? Let us take Dr. Johnson's advice, and clear our minds of cant. "An army," as Wright says, "on going out on active service goes from the sanitary conditions of civilisation straight back to those of barbarism. . . . In war the doors are everywhere opened

wide, both to the direct conveyance of infection by the excreta, and to its indirect conveyance by means of contaminated water. . . . On service, proper sanitary arrangements are very often impossible. We may think, for instance, of the situation of men in the trenches under fire. . . . When it comes to a tight place the alternative which will present itself will be that of drinking a polluted water or none. . . . It will, by the very nature of the case, be out of question to apply ordinary sanitary measures in an effective manner. . . . Infection spreads not only among the troops in the field, but also among the soldiers in hospital."

The *Daily Chronicle*, October 3, says, "It is reported that 800 Germans, on the lines between Brussels and Antwerp, are suffering from typhoid fever."

That the protective treatment is indeed protective we all know. It is the experience of the nations of the earth; and the whole world is agreed about it. France, India, Canada, the United States, Italy—let alone our enemies—are of one mind. Take only four instances:—

1. *British Army in India.*—"The histories, as regards typhoid fever, of 19,314 soldiers, whose average period of service abroad was twenty months, were carefully followed, and every precaution possible was taken to verify the diagnosis bacteriologically. Of this number 10,378 were inoculated, and 8936 not inoculated. The case incidence of typhoid fever among the inoculated was 5·39 per 1000, and among the non-inoculated 30·4 per 1000."—*Report of Anti-Typhoid Committee*, 1912.

2. *United States Army.*—"Inoculation was made compulsory in the American Army in 1911, and has practically abolished the disease. In 1913 there were only three cases and no deaths in the entire army of over 90,000 men."—Sir W. Leishman, *Brit. Med. Journ.*, August 22, 1914.

3. *French Army.*—In 1912 typhoid broke out in the barracks at Avignon. Of 2053 men, 1366 were protected and 687 were not. The non-protected had 155 cases, with twenty-one deaths; the protected had not one case. The protective treatment was made compulsory last winter in the French Army; and, in special circumstances, among the reservists.—*Lancet*, January 4, 1913.

4. *Canadian-Pacific Railway.*—Throughout the "railway camps" in Alberta, during 1911, among 5500 protected there were only two cases of typhoid; among 4500 non-protected there were 220 cases.—*Brit. Med. Journ.*, June 6, 1914.

It remains to be noted: (1) That the vaccine contains no living germs of any sort. (2) That the treatment, though it gave good results in the South African War, has been improved since that time. (3) That the avoidance of exertion and excitement, on the day of treatment, is a great safeguard against any disturbance of the general health. (4) That, when time allows, it is always best to give the vaccine not all in one dose, but in two, or even three graduated doses, with a few days between each dose.

Sir Almroth Wright, by whose hands the gift of this treatment came to us, greatly desires that the treatment should be made compulsory, as in other armies, so in ours. Surely it is part of "my duty to my neighbour" that I should not, by having typhoid, expose him to the risk of infection from me. And it is certain that a soldier down with typhoid fever is not only useless against the enemy, but dangerous to his own friends.

STEPHEN PAGET.

THE BRITISH ASSOCIATION IN VICTORIA.

MELBOURNE, AUGUST 20.

On their arrival from Adelaide by three special trains on Thursday, August 13, the visitors were taken to their quarters, but soon most of them found their way to the reception room at the University. The lecture theatres of the University, and of the Teachers Training College, afforded ample accommodation for all the sections, and are in the same grounds.

In the evening the Governor-General received members at Government House, and some 3000 guests were present at a brilliant function. On Friday afternoon, August 14, a graduation ceremony was held in Melba Hall, when nearly 1000 persons were present. The degree of D.Sc. was conferred on the president, Prof. W. Bateson, and on Sir Edward Schäfer, Prof. H. E. Armstrong, Dr. F. W. Dyson, Sir Thomas Holland, Prof. W. J. Pope, Prof. A. W. Porter, Sir Ernest Rutherford, Prof. Johannes Walther, Prof. W. M. Davies, Prof. C. G. Abbott, and Prof. Luigi Luiggi. At a later hour the Lord Mayor held a reception at the Town Hall, which was largely attended. In the evening the president delivered the first half of his address in the auditorium in the presence of more than 2000 persons. The Governor-General and the State Governor were present, and proposed and seconded the vote of thanks.

On Monday afternoon, August 17, Prof. E. B. Poulton delivered a discourse on "Mimicry" before a very large and appreciative audience. In the evening the Government of Victoria held a reception at the Public Library, Picture Gallery, and National Museum, the buildings for which are in communication. The guests, numbering about 4000, were received by the Premier, Sir Alexander Peacock, Lady Peacock, and by the Chief Secretary, the Hon. John Murray. The ample accommodation afforded by the large rooms prevented undue crowding, and the evening was most enjoyable.

On the following afternoon the Overseas members were entertained at the Botanic Gardens by the members of the scientific societies of Victoria. The weather was delightful, and the magnificent gardens were greatly admired by the guests. The president planted a memorial tree (*Cupressus macrocarpus*) to commemorate the historic visit of the association. In the evening

Dr. F. W. Dyson delivered the second discourse on "Greenwich Observatory and its Work."

A number of week-end excursions were made, and, owing largely to the beautiful, though unseasonable, weather, were all successful. The greater number of the excursionists were Overseas members, the Australian members being restricted largely to the official leaders and experts in what may be called "side-issues." Thus, a geological excursion would be accompanied by someone who could name plants, and so on.

About forty went by special train to Bacchus Marsh to inspect the Permo-Carboniferous glacials. Drs. Hall and Pritchard were the leaders, and Messrs. Sweet and Brittlebank, who discovered and worked out the beds, were present to help, and the main features were clearly seen.

The Surveyor-General, Mr. J. M. Reed, led a party by train and by coach over the dacite mountains to Marysville. Botanists, zoologists, and sightseers had a splendid, though somewhat arduous, time. Dr. C. S. Sutton and Mr. James Cuming, who was the host for the occasion, took a very large number by train to Warburton and Cement Creek. This is the home of big trees, though most of the giants have vanished. A visit was paid to the works of Messrs. Cuming, Smith and Co., where a number of chemical products from the eucalyptus are prepared on a fairly large scale. The naturalists revelled in the rich fern gullies with their wealth of zoological and botanical novelties.

A long day's excursion to the Macedon district was made possible by the generosity of the Automobile Club of Victoria, which provided cars. Prof. Skeats and Dr. Summers were the leaders, and the remarkable series of igneous rocks, for which the locality is famous, were well explored.

Prof. A. J. Ewart and Mr. R. Grimwade took a very large party by train along the narrow gauge track to Emerald. The mountain forest country was seen and large nurseries for raising fruit trees, and the Bosisto experimental oil-farm were visited. At the latter place, Messrs. Grimwade and Co. are cultivating scent plants, and have large experimental plantations of eucalyptus. Botanically, the excursion was a great success, as many typical Australian plants were seen.

A large party went by special train to Ballarat, the second city of the State. The mayors of the twin cities were most hospitable, and Mr. Wm. Baragwanath, the geological surveyor in charge of the district, demonstrated the leading features. The Government geologist, Mr. H. Herman, took another large party to Bendigo, where the famous "saddle" reefs were the chief source of attraction. The structure of the field was very clearly seen, and the lavish hospitality of the mayor and of the leading citizens was highly appreciated. Both here and at Ballarat, the plentiful loan of motor-cars made the inspection of wide areas of the surrounding country possible.

An excursion to the National Park at Wilson's Promontory, where 150 square miles of mountainous country is reserved as a sanctuary for animals and plants, had been planned by steamer. Almost at the last moment, the war troubles prevented the loan of the vessel. However, Mr. C. Catani, chief engineer of the Public Works Department, the leader, and especially Mr. J. A. Kershaw, curator of the National Museum, managed an overland transport, and the visit was thoroughly enjoyed by the small number who went.

Visits were paid to the Central Research Farm at Werribee under Dr. S. S. Cameron, Director of Agriculture, and to the Bacchus Marsh irrigated area under Dr. Elwood Mead.

Besides these official excursions, a large number were made under private guidance, and many special entertainments were given.

The meeting was, from all points, most successful; the Victorian members numbered 1998, and the details of organisation were under the control of Prof. Baldwin Spencer.

T. S. HALL.

NOTES.

THE Research Defence Society has prepared an instructive leaflet upon the subject of protection against typhoid fever, dealt with by the honorary secretary of the society, Mr. Stephen Paget, elsewhere in the present issue of NATURE. The society sends out supplies of this leaflet, and makes arrangements for providing the treatment, free of charge. Application should be made to the hon. secretary, Research Defence Society, 21 Ladbroke Square, London, W.

IT is reported by a Reuter message from Smyrna that an earthquake which occurred at midnight on Saturday, October 3, partly destroyed the towns of Isbarta and Burdur in the province of Konia, Asia Minor.

THE death occurred on September 30, at eighty-eight years of age, of Sir Henry Littlejohn, late president of the Royal College of Surgeons, Edinburgh, professor of forensic medicine in the University of Edinburgh in the years 1897–1906, medical officer of health for Edinburgh from 1862 to 1908, and the author of many publications on legal medicine and public health.

THE attention of our readers may be usefully directed to the joint propaganda of the Fisheries Organisation Society and the National Deep Sea Protection Association. These bodies have issued a reprint of an article, by Mr. Stephen Reynolds, on fish-food in wartime, and a series of very practical recipes and hints on cooking and buying fish, in which particular attention is directed to the use of cured herrings and other fish. The Board of Agriculture and Fisheries also issue leaflets relating to the further utilisation of fish and salted herrings as food. It is very desirable that the propagandist efforts to which we refer should be made as widely known as possible. Deep-sea fishing is suffering severely from the restriction of the fishing grounds, from actual war losses, and from the diversion of

very many vessels and men to the dangerous task of mine-sweeping; and with very great loyalty the fishing trade in general has combined to keep prices as low as possible. The herring fisheries are suffering even more severely from the loss of their great continental markets for salted fish: it will be unfortunate in every way if the yield of this industry should be gravely diminished, and the only hope seems to be in the securing of the normal stock of pickled herrings for domestic use and future trade, by the State. The Fisheries Organisation Society is an outcome of the recently published report of the Inshore Fisheries Committee: it aims at the further development of the smaller sea and coastal fisheries by various methods. Its offices are at Queen Anne's Chambers, Tothill Street, Westminster. At no other time than the present could this organisation be of greater service to the country, and we hope that many of our readers may be inclined to make themselves acquainted with its work.

We have received from Mr. Francis Edwards, of 83 High Street, Marylebone, W., a catalogue of "books about birds," together with a certain number of publications of learned societies, the whole comprising between two and three hundred items.

According to the *Victorian Naturalist* for August, an attempt is to be made to introduce the lyre-bird into Tasmania. Mr. D. le Souëf, who was consulted in regard to the probable cost of the experiment, gave the opinion that the birds could be trapped for about 5*l.* per pair, adding that suitable food during the period of confinement could be supplied by the Melbourne Zoological Gardens.

Free-swimming nematode and littoral oligochæte worms from the salt Chilka Lake, on the Orissa coast of Bengal, form the subject of two articles, respectively by Dr. F. H. Stewart and Major J. Stephenson, in vol. x., part 4, of Records of the Indian Museum. All the four genera of the former group found in the lake-fauna are cosmopolitan, and for the most part marine types; but at least four of the Chilka species, referable to three genera, are regarded as new.

In vol. ii., No. 5, of the *Austral Avian Record,* the editor, Mr. G. M. Mathews, makes further emendations in his list of Australian birds. Among these may be noted the creation of no fewer than a dozen new generic names for various long-established species. To many naturalists this will seem an altogether unnecessary proceeding, and, in any case, such inelegant and unwieldy compounds as Purnellornis, Alphachlamydera, Alphacincla, and the like, are to be deprecated.

To the October number of the *Museums Journal* Dr. F. A. Bather contributes an instructive article on museums and national service, in which special reference is made to the various branches of research work now carried on at the Natural History Branch of the British Museum. The amount of work of direct practical utility yearly accomplished there would, it is claimed, surprise even those familiar with that establishment, attention being also directed to the cosmopolitan character of these researches. At present the museum has not a health department, with special facilities for bacteriological work and the practical study of hygiene; but it is suggested that such an addition would form an important extension of the museum's already manifold functions.

In connection with the above, reference may be made to an article in the same issue by Mr. F. Leney, of the Norwich Museum, on the insurance of museums and their contents against fire and damage from other causes. The article formed the subject of a paper read at the recent Museum Conference at Swansea, where an instructive discussion took place at the close of the reading. Metropolitan Government museums are, we believe, uninsured, and the matter relates, therefore, solely to local institutions. The usual practice, it appears, is to insure the buildings separately from the collections, and generally against fire alone. Loan collections are, however, habitually insured against risks of all kinds. In the discussion, Dr. Hoyle referred to the progressive appreciation in value of many objects in museums, and the consequent automatic under-insurance of collections.

Bird-skins in museums, it appears, form a rich hunting-ground for students of bird-lice (Mallophaga), as those parasites are generally preserved with the skins of the birds they infest. Advantage of this has recently been taken in the Indian Museum, Calcutta, where the store-skins of game-birds and the crow-tribe have been carefully searched, and the dried parasites picked out. The latter were sent to Prof. V. L. Kellog, of Stanford University, California, by whom and his colleague, Mr. J. H. Paine, the collection is described in vol. x., part 4, of Records of the Indian Museum. That the bird-lice found in any individual kind of bird-skin are really native to that particular species, appears, in most cases at any rate, to be beyond doubt, and, as the result of their study of the Calcutta collection, the authors of the paper have felt themselves justified in describing no fewer than thirteen species as new.

The subject of "glazed frost" is always interesting, owing to its somewhat rare occurrence, and possibly to some extent to the uncertainty of part of the physical process involved in its formation. The term is now generally adopted for the smooth coating of ice which covers objects, and is usually formed when rain, consisting of super-cooled water drops, strikes the ground or other objects, but may "very occasionally" be formed in other ways. To the Journal of the Meteorological Society of Japan for May last Dr. T. Okada contributes some useful notes on the phenomenon, and quotes cases of its occurrence in that country, together with detailed observations. His calculation shows that, in the case under consideration, "the conduction and evaporation of raindrops falling through ice-cold layers of the atmosphere will be sufficient to cool them many degrees below the freezing point." As pointed out elsewhere by Mr. E. Gold, the difficulty appears to be to explain why small drops do not solidify in falling through the air.

IN the *Mathematical Gazette* for July (vi., 12), Prof. Harold Hilton proves that any twisted cubic curve may be displaced so that every point is moving perpendicular to its tangent, provided that the curve is screwed about a certain fixed axis.

THE resistance of road vehicles to traction is commonly regarded as the sum of two parts, one due to rolling friction on the ground and the other due to sliding friction at the axle. In a recent note (Venice, Carlo Ferrari, 1914) reprinted from the *Atti del R. Istituto veneto*, lxxiii. (2), pp. 931–46, Prof. T. Levi Civita, by considering the conditions of equilibrium, establishes the interdependence of these two resistances, and obtains new formulæ determining the total resistance. The title of the paper is "Sforze di regime e sforze d'avviamento per veicoli trainati."

FROM the Department of Lands and Surveys of Western Australia we have received a copy of its "Geodetic Tables." This publication contains two tables, of which one gives the logarithms of the number of links in 1″ of latitude, and of longitude, and the other gives the logarithms of the seconds of the arc-versines of spheroidal arcs of parallels 1″ in length. In each case the tables cover the range of 50° from the equator southwards. The tables are based on the auxiliary tables of the Survey of India, the values for the additional ten degrees having been specially computed. A short introduction explains the method of using them, and they should be of use to land surveyors who wish to control their work by means of the triangulation stations of the department.

IT was proved by Prof. Arnold Emch in the *American Journal of Mathematics* for October, 1913, that in every closed convex curve which is analytic throughout, at least one square can be inscribed. That at least one square can be circumscribed about such an oval curve is now proved by Prof. Tsuruichi Hayashi in the Bulletin of the American Mathematical Society, xx., 9, where he also obtains a parametric representation of the curve in tangential co-ordinates. His proof of the possibility of circumscribing the square about an oval curve is very simple. You can evidently circumscribe a rectangle having its sides parallel to any given direction. Now turn the direction round until the longer side becomes the shorter one. Then in some intermediate position the two sides will become equal, and the figure is then a square. It will be interesting and easy for mathematically inclined readers of NATURE to reconstruct from this material a corresponding proof for the inscribed square if they have not seen Prof. Emch's paper.

IN Yamagata, Japan, is a small lake called the Lake of the Floating Islands, discovered about the year 1340, which has from that time attracted the attention of many poets and literary men. A report on the mysterious movements of these islands drawn up by a party under Prof. S. Kusakabe is published in the Science Reports of the Tohoku Imperial University (Sendai), iii., 2. The floating islands, which at times number no fewer than sixty, are found to be continually changing their position, moving first one way and then the other. In the first series of observations, wooden floats were placed in the lake showing the distribution of the various currents; subsequently a model of the lake was constructed, and it was found possible closely to reproduce the various movements of the surface. When both water and wind currents were taken into account, the actual behaviour of the islands was found to be quite in accordance with theory and experiment. The islands originate from masses of vegetable *débris* which are first carried to the surface by bubbles of gas; then reeds commence to grow from seed on them; sometimes the mass becomes top-heavy and overturns, and reeds grow on the other side, until the island has grown sufficiently large in extent to secure stability.

THE September number of *Terrestrial Magnetism and Atmospheric Electricity* contains reports of the work done by the magnetic survey ship *Carnegie* during her second cruise round the world and during a more recent journey from New York along the Gulf Stream to Hammerfest. Along the line of the latter route the values of the deviation of the compass to the west of true north were found to be in general greater than the values given in the British and American charts by amounts which reach 1·3° in the former and 2·2° in the latter chart. The atmospheric electric observations taken during the voyage round the world lead to the conclusion that over the sea the potential gradient is of the same order as that over land, the radio-activity is smaller, while the specific conductivity is larger, than that over land. The conductivity appears to be independent of the radio-activity, although, like the radio-activity, it is greater for air which has been in contact with land than for air which has not during the week before the observations on it are made.

THE Journal of the Washington Academy of Sciences for August 19 contains two interesting optical papers. The first, by Prof. P. G. Nutting, of the Eastman Research Laboratory, gives the results of a series of measurements of the focal length of the human eye for light of different wave-lengths within the visible spectrum The author finds that while for a water lens the focal length increases by about 5 per cent. from the extreme blue to the red end of the spectrum at a rate which is fairly uniform, for many human eyes the increase, although of about the same amount, is confined to the ends of the range, the change over the middle half not exceeding 1 per cent., so that these eyes are nearly achromatic. The second, by Mr. F. E. Wright, of the Geophysical Laboratory, describes a new method of determining the refractive index of a mineral by the petrographic microscope. A stop below the condenser covers half the field, and its inverted image is formed between the stage and the low-power objective. In the same plane as this image a second stop is placed, and the distance of the edge of the second from that of the image of the first so adjusted that the field is nearly dark. In these circumstances, if a grain of mineral immersed in a liquid of refractive index not exactly equal with that of the mineral is placed on the microscope stage, the edges of the grain appear some

brighter, some darker, than the field, and a liquid having the same refractive index as the mineral can be quickly chosen.

PRACTICAL methods of determining the critical loads for long struts of varying section have attracted some attention recently. The latest contribution to the subject is given in an article in *Engineering* for October 2 by Messrs. L. Bairstow and E. W. Stedman, of the National Physical Laboratory. The method described seems to be comparatively easy to apply, and has the advantage of being applicable with equal ease to the simplest or to the most general case. It was devised originally for finding the critical loads of wooden struts as used in aeroplane construction. An assumed critical load for the strut is guessed or obtained by an approximate method such as taking Euler's law for a uniform strut of the average section. Curves for $-d^2y/dx^2$, dy/dx and v, which comply with the conditions imposed, are then drawn by a process of trial and error described in the article. If the assumed value of the critical load has happened to be correct, the ordinate of the dy/dx curve becomes zero at the middle of the strut (for a strut hinged at both ends). If the assumed value has been incorrect, the ordinate becomes zero at some other point. After two attempts, a very close approximation to the value of the critical load is reached.

ERRATUM.—In NATURE of September 24, p. 95, col. i., for Dr. S. N. Shannus read Dr. H. S. Stannus.

OUR ASTRONOMICAL COLUMN.

A NEW COMET.—The *Times* of October 3 publishes a telegram from South Africa announcing the discovery of a bright comet by Mr. Lunt at the Royal Observatory, Cape Town, on September 18. Mr. Wood, of Johannesburg, computed the orbit, and the following is the ephemeris given:—

	Right Ascension h. m. s.		Declination ° ′
Oct. 1 ...	22 48 48	...	−26 44
5 ...	22 23 36	...	17 41
9 ...	22 8 44	...	11 11
13 ...	21 59 24	...	−6 34

Perihelion passage took place on August 5. While the comet is decreasing its southern declination and reaching a better position for observation in this country its brightness is stated to be fading fairly rapidly owing to the increasing distance from the sun. On October 9 the comet will be situated in the constellation of Aquarius, a little below the third magnitude star gamma.

The following elements, based by Mr. Wood on observations made on September 21, 24, and 27, have been since communicated by the Royal Astronomical Society:—

$$T = 1914 \text{ Aug. } 4{\cdot}99 \text{ G.M.T.}$$
$$\left.\begin{array}{l}\omega = 270^\circ\ 19' \\ \Omega = \ \ 0^\circ\ 22' \\ i = \ 77^\circ\ 51'\end{array}\right\} 1914{\cdot}0$$
$$\log q = 9{\cdot}8543$$

COMET 1913*f* (DELAVAN).—Delavan's comet is now badly situated for evening observation, so most should be made of the morning hours. The object is rapidly decreasing its northern declination and moving westward, and will pass perihelion on October 26. It is now situated in the constellation of Canes Venatici, and on October 10 will not be far from the third magnitude star, 12 Canes Venaticorum. The following eight-day ephemeris is taken from *Knowledge* for August last:—

	Right Ascension h. m. s.		Declination ° ′
Oct. 10 ...	12 56 44	...	+38 56
18 ...	13 37 56	...	32 57
26 ...	14 11 50	...	26 45
Nov. 3 ...	14 40 44	...	+20 40

THE RETURN OF ENCKE'S COMET.—The short-period comet known as Encke's comet, for he it was who first calculated its elements, although Pons, of Marseilles, actually discovered it in the sky, was due to return this autumn, its period being about three and one-third years. It is now reported (*Daily Telegraph*, October 2) that it has been observed from the Russian Observatory at Simeis in the Crimea, this information having been received from Prof. Backlund, the director of the Pulkovo Observatory. It is situated in the constellation of Perseus. Encke's comet is of historical interest for several reasons. It was only the second instance of the recognised return of a comet, Halley's comet having preceded it by sixty-three years. It was also the first example of a new class of celestial objects revolving round the sun within the orbit of Saturn and exhibiting certain planetary affinities in the manner of their motions.

ENHANCED LINES AND THE PRESENCE OF HYDROGEN.—No. 85 of the Contributions from the Mount Wilson Solar Observatory is devoted to some electric furnace experiments on the emission of enhanced lines in a hydrogen atmosphere. The author, Mr. A. S. King, used in this research the vertical Rowland grating spectrograph described in this column on September 24. The experiments included the production of the enhanced lines with the furnace in a partial vacuum and in hydrogen at varying pressures up to one atmosphere, and the use of greatly different amounts of titanium. After describing the details of the experiments Mr. King sums up his results in three brief but interesting paragraphs. The experiments failed to show any effect of a hydrogen atmosphere in strengthening enhanced lines. The enhanced lines appear in the furnace at low pressures with equal ease whether hydrogen is present or whether the furnace contains a residue of air. No material effect on the relative intensities of enhanced lines is indicated, even when widely differing amounts of titanium vapour at low pressure and at the same temperature are employed. Increasing the pressure of hydrogen, the temperature being held as nearly constant as possible, causes a progressive weakening of the titanium enhanced lines, until at atmospheric pressure only traces of the strongest are visible in the furnace spectrum. Mr. King finally directs attention to the bearing of these results on the study of stellar atmospheres and the value of the strength of enhanced lines as a criterion not only for stellar temperatures but for different regions and levels of the solar photosphere.

THE LEEDS ASTRONOMICAL SOCIETY.—Vol. xxi. of the Leeds Astronomical Society contains the Journal and Transactions for the past year. The volume is edited by Mr. C. T. Whitmell, and gives a good account of the activity of this society. At each of the seven meetings which took place a paper on some definite subject was read, and these are reproduced more or less in full in this report. Thus some of the contributions dealt with the spectroscope, Uranus as a view-point, history of astronomy, etc. Other work of the society is summed up in the latter part of the volume.

GEOLOGY IN BRITISH AFRICA.

MEMOIR No. 6 of the Geological Survey of South Africa, by A. L. Hall, on "The Geology of the Murchison Range and District," deals with picturesque features of the Drakensberg scarp. Plate xv. finely illustrates the youthful nature of the Groot Letaba River (Fig. 1), which is represented (p. 29) as having cut back into the mature drainage-system of the M'Thlapitsi. The banded ironstones near Thabina (p. 66), associated with metamorphosed sediments, are regarded as also of sedimentary origin, although they are now composed of magnetite. We believe that this view must be generally accepted, and it has an obvious bearing on theories of the origin of the sheet-like magnetite ores of Sweden. Pp. 124 to 130 contain an interesting account of the formation of hybrid rocks between syenite, pyroxenite, and limestone. The limestone now contains olivine,

FIG. 1.—Gorge cut by the Groot Letaba River in its recession from the escarpment; the stream now receives water captured from the M'Thlapitsi.

magnetite, and apatite. The Olifants River mica-fields come within the scope of this memoir (p. 153). We notice (p. 19) that "neck" is used, perhaps unwisely, in its English form for a notch produced by weathering.

Sheet 13 of the geological map, and the accompanying memoir on "The Geology of the Haenertsberg Goldfields" (1914), are concerned with similar country, and the great scarp of the Black Reef quartzite appears conspicuously on the map. The memoir and map (Sheet 12) of the Pilandsberg, a great igneous centre north of the Witwatersrand and Rustenburg, are due to W. A. Humphrey, and direct attention to a region of great petrographic interest. The rocks have been previously described; they are syenites rich in alkalies, forming a great wall-like ring that surrounds a region of tuffs and lavas, also of the alkali type. Aegirine, leucite, and nepheline occur in the volcanic rocks. The ring suggests a "cauldron-subsidence," and an oozing up of matter along the marginal crack, as described by E. B. Bailey in the Cruachan area. The circular group of rocks is shown to be later than the Waterberg system, but has no kinship with the Drakensberg outflows. The map of this basal relic, sixteen miles across, forms one of the most striking lessons in volcanic structure with which we are acquainted.

The annual report of the Geological Survey of South Africa for 1912, published at the close of 1913, contains a summary by the director, H. Kynaston, both in Dutch and English, a memoir by him on the Marico and Rustenburg districts, one on the western Witwatersrand by E. T. Mellor, and a finely illustrated memoir by A. T. Hall on the country between Belfast and Middelburg. A. L. du Toit reports on Pondoland.

It is difficult in a few notes to do justice to the large amount of mineral and petrographic information issued regularly in the Transactions of the Geological Society of South Africa. In vol. xiv. (1912) p. 71, G. S. Corstorphine records a further occurrence of diamond in eclogite from the kimberlite pipe of the Roberts Victor Mine, Orange Free State. He still maintains that such eclogites are segregations from the peridotite (kimberlite) magma. C. T. Mellor (p. 99) contributes a detailed revision of the Lower Witwatersrand system, with a map and sections. He concludes that the conglomerates indicate a steady progression from deposits on the seaward margin of a delta up to true beaches on a shore. In vol. xv., p. 31, A. W. Rogers publishes his correlation of the Nieuwerust, Malmesbury, and Ibiquas Series of the Cape Province with the Nama system of German South-West Africa. The three series are now shown to have the sequence given above, the Nieuwerust beds being the oldest. P. Range's paper (p. 63) on the topography and geology of the German South Kalahari contains an interesting account of the nature of "pans." The author points out that good supplies of water are within reach of the dry lands of the Kalahari, in the Karroo and Nama beds that underlie the calcareous sandstone and dune-sand of the surface.

The Proceedings of the society include a lengthy discussion of Mr. Mellor's stratigraphical paper, and a presidential address by R. B. Young on the problem of the Rand Banket (1911, p. xxi.). Dr. Young argues against the detrital origin of the auriferous pyrite in the conglomerates. In vol. xv. (p. 83) he urges that the black colour of the quartz in the banket is due to dark inclusions, and he shows by thin sections how these are commonly related to shattered areas in the pebbles. The colour, then, arose after the vein-quartz had become included in the conglomerate.

Prof. Schwarz (*ibid.*, vol. xvi., 1913, p. 33) revives interest in the contacts of granite and schist near Cape Town, which were described by Playfair and Basil Hall in 1813, and by Clarke Abel in 1818. He does not mention Darwin's fruitful observations; but he accepts the view that the granite has absorbed the slates, and that the parallel flakes of biotitic matter represent residues from the sedimentary series. The advance of the granitic matter into the slate has allowed of the development (p. 35) of felspar crystals 2 in. long as replacements of digested matter. F. E. Studt provides (p. 41) an important regional paper on Katanga and Northern Rhodesia, involving a review of South African structure as a whole. He believes that the extensive lava-flows of East Africa were connected with subsidences which date back to Middle

Carboniferous times (p. 95), and that the Karroo strata of Katanga and Rhodesia were formed in the lowered areas. The "graben" of the great lake region is of much younger age. H. S. Harger, in his presidential address (vol. xvi., p. xxii.), points out that the Drakensberg lavas are of Jurassic age, and probably extended at one time right across the Free State. He is concerned with the immense amount of subsequent denudation, but does not explain how the "vast peneplain" over the entire Karroo (p. xxviii.) came about, if the surface remained high above sea-level. A great inland lake might, of course, supply a base-level. He contrasts the periods of great river-action with those of subsequent desiccation, and gives striking illustrations of denudation by sand-storms in German South-West Africa. May we ask that this energetic society should consider those members who cannot promptly bind the Transactions? They have a way of falling to pieces when one cuts the pages which renders them very liable to denudation.

F. Oswald, well known for his researches in Armenia, has described "The Miocene Beds of the Victoria Nyanza and the Geology of the Country between the Lake and the Kisii Highlands" (Quart. Journ. Geol. Soc. London, vol. lxx., 1914, p. 128). His journey through a fly-infested region was undertaken to collect vertebrate remains from lacustrine strata, which underlie extensive flows of nepheline-basalt. C. W. Andrews describes the mammalia, including Dinotherium and two anthracotheres, and R. Bullen Newton shows that the associated freshwater mollusca represent existing species. The mammalia, however, assign the deposits, which were formed probably in a delta, to the Burdigalian epoch, and the history of the Victoria Nyanza is thus carried back into the middle of Cainozoic time.

R. B. Newton enters the African field in another paper (Records of the Albany Museum, Grahamstown, vol. ii., 1913, p. 315), in which he shows that the extensive Alexandria formation of the Cape Province is of Cainozoic age, and distinct from the Cretaceous strata occurring near East London. Several new molluscan species are represented in a beautiful series of photographic plates.

A. E. V. Zealley ("Zinc and Lead Deposits of Broken Hill, N. Rhodesia," South African Journ. Sci., vol. viii., 1912, p. 396), remarks that the phosphates in this area, including the beautiful deposits of hopeite, are connected with the decomposition of a bone-breccia, and that vanadinite arises in connection with the zinc and lead phosphates in a way which suggests that vanadium occurs also in the bones.

THE INSTITUTE OF METALS.

In the study of the constitution of alloys, as well as in the practical and commercial use of both pure metals and alloys, that form of heat treatment known as annealing plays an important part, and a complete knowledge of the effects of various temperatures and conditions of annealing is of vital importance. This statement is not invalidated by the fact that many of our large metal works conduct their annealing operations in the most crude and haphazard way, a state of affairs which is, happily, becoming a thing of the past. In this connection it is interesting to note that one-third of the papers read at the recent meeting of the Institute of Metals deal, to a greater or less extent, with this important subject. J. Phelps shows that the presence of hydrogen in the atmosphere surrounding silver which is being annealed, increases the temperature required to obtain complete softness in thirty minutes, from below 150° C. to about 300° C. F. Johnson emphasises the necessity of annealing Admiralty brass castings to a temperature of about 700° C. Bengough and Hanson show that copper tested to destruction in an oxidising atmosphere has an elongation four times as great, and a maximum stress one-third as great, as that obtained when the test is carried out in a neutral atmosphere such as carbon dioxide.

Bengough and Hanson's paper also contains much interesting information as to the tensile properties of copper at high temperatures. They show that this metal fits in very well, on the whole, with Rosenhain's amorphous theory, the fracture changing from a ductile, crystalline one at low temperatures, to a non-ductile, intercrystalline, and very brittle one at high temperatures. A remarkable difference, however, is that Rosenhain and Ewen found that the intercrystalline fracture occurred within a few degrees of the melting point, whereas the present workers have found that, in the case of copper, it is evident as low as 720° C., or about 350° C. below the melting point.

From time immemorial, manufacturers of zinc-copper alloys have known that, at temperatures somewhat below a red heat, 60/40 brass becomes very brittle, recovering its normal strength as it cools. This fact was referred to by Bengough and Hudson in a paper read to the Institute of Metals in September, 1910. At the next meeting Carpenter and Edwards showed that there was an arrest point occurring at about 470° C. in the heating and cooling curves of this alloy. They pointed out that this could be explained by assuming either (1) that there was a polymorphic modification of the β constituent at this temperature, or (2) that the β splits up into $\alpha+\gamma$. On microscopic and other grounds they accepted the latter view. In the discussion which followed the reading of the paper, Mr. Hudson, amongst others, confessed himself unable to accept Prof. Carpenter's interpretation. Since then the fray has raged more or less continuously between the supporters of the two theories, and at this meeting a paper has been read by Mr. Hudson, which, in the opinion of the writer, definitely settles the question in favour of the polymorphic theory. Briefly, the β constituent has been synthetised from α and γ at temperatures below 470° C., *i.e.* at a temperature at which the "decomposition theory" supposes that it does not exist in equilibrium. This result was obtained by annealing a piece of 70/30 brass in contact with a piece of zinc at a temperature ranging between 420° C. and 430° C.; after annealing for several days, a section was cut at right angles to the junction of the two metals, and it was found that β was present.

The third part of Arnold Phillip's "Contribution to the History of Corrosion" consists in a refutation of the statement (made by Bengough and Jones in their "Report to the Corrosion Committee") that coke in condenser tubes does not promote corrosion. He brings forward evidence to prove that the reverse is the case.

Thorneycroft and Turner continue the work commenced some years ago by Prof. Turner on the volatility of metals *in vacuo*. The present paper describes the results of experiments on the zinc-copper series, and the authors show that those alloys containing more than 40 per cent. of copper can be quantitatively separated into their constituent metals by distillation *in vacuo*, while in the case of those which contain less than 40 per cent., part of the copper comes over with the zinc.

Amongst other papers read at the meeting is an interesting one by Captain Belaiew, which has been reprinted already in Nature (p. 107), a description of the Schoop process of spraying metals by R. K. Morcom, and a paper by S. W. Smith on the surface tension of molten metals.

THE AUSTRALIAN MEETING OF THE BRITISH ASSOCIATION.

SECTION M.

AGRICULTURE.

Address by A. D. Hall, M.A., F.R.S., President of the Section.

The president of a section of the British Association has two very distinct precedents before him for his address; he can either set about a general review of the whole subject to which his section is devoted, or he can give an account of one of his own investigations which he judges to be of wider interest and application than usual. The special circumstances of this meeting in Australia have suggested to me another course. I have tried to find a topic which under one or other of its aspects may be equally interesting both to my colleagues from England and to my audience who are farming here in this great Continent. My subject will be the winning of new land for agriculture, the bringing into cultivation of land that has hitherto been left to run to waste because it was regarded as unprofitable to farm. To some extent, of course, this may be regarded as the normal process by which new countries are settled; the Bush is cleared and the plough follows, or under other conditions the rough native herbage gives way to pasture under the organised grazing of sheep or cattle. I wish, however, to deal exclusively with what are commonly termed the bad lands, inasmuch as in many parts of the world, though recently settled, agriculture is being forced to attack these bad lands because the supply of natural farming land is running short. In a new country farming begins on the naturally fertile soils that only require a minimum of cultivation to yield profitable crops, and the new-comers wander further afield in order to find land which will in the light of their former experience be good. Before long the supply is exhausted, the second-class land is then taken up until the stage is reached of experimentation upon soils that require some special treatment or novel form of agriculture before they can be utilised at all. Perhaps North America affords the clearest illustration: its great agricultural development came with the opening up of the prairies of the Middle West, where the soil, rich in the accumulated fertility of past cycles of vegetation, was both easy to work and grateful for exploitation. But with the growth of population and the continued demand for land no soils of that class have been available for the last generation or so, and latterly we find the problem has been how to make use of the arid lands, either by irrigation or by dry-farming where the rainfall can still be made adequate for partial cropping, or, further, how to convert the soils that are absolutely poisoned by alkali salts into something capable of growing a crop. You yourselves will supply better than I can the Australian parallels; at any rate we in England read that the wheat-belt is now being extended into districts where the low rainfall had hitherto been thought to preclude any systematic cropping.

Now, the fact that the supply of naturally fertile land is not unlimited reacts in its turn upon the old countries. During the 'eighties and 'nineties of the last century the opening up of such vast wheat areas in America, Argentina, Australia, and the development of the overseas trade, reduced prices in Europe to such an extent that in Great Britain, where the full extent of the competition was experienced, the extension of agriculture came to an end despite the continued increase of population. The area of land under cultivation has declined but little despite the growth of the towns, but the process of taking in the waste lands stopped, and much of the land already farmed fell back from arable to cheaper pasture. But as soon as production in the newer countries failed to keep pace with the growth of population, prices began to rise again, and we are now in the Old World endeavouring to make productive the land that has hitherto been of little service except for sport and the roughest of grazing. Even the most densely populated European countries contain great areas of uncultivated land; within fifty miles of London blocks of a thousand acres of waste may be found, and Holland and Belgium, perhaps the most intensively cultivated of all Western

countries, possess immense districts that are little more than desert. Of the European countries, Germany has taken the lead in endeavouring to bring into use this undeveloped capital; her population is rising rapidly, and her fiscal policy has caused her to feel severely the recent increase in the prices of foodstuffs, which she has determined to relieve so far as possible by extending the productivity of her own land. It has been estimated that Germany possesses something approaching to ten million acres of uncultivated land, and a Government department has been created to reclaim and colonise this area.

Before dealing with the processes by which the rough places of the earth are to be made straight, there is one general question that deserves consideration: Is it more feasible to increase the production of a given country by enlarging the area under cultivation, or by improving the methods of the existing cultivators? There is without doubt plenty of room for the latter process even in the most highly farmed countries: in England the average yield of wheat is about 32 bushels per acre—a good farmer expects 40; the average yield of mangolds, a crop more dependent upon cultivation, is as low as 20 tons per acre when twice as much will not be out of the way with good farming. A large proportion of the moderate land in England is kept in the state of poor grass—even as grass its production might be doubled by suitable manuring and careful management, while under the plough its production of cattle-food might easily be trebled or quadrupled. Why, then, trouble about adding to the area of indifferent land when so much of what has already been reclaimed, upon which the first capital outlay of clearing, fencing, roadmaking, etc., has been accomplished, is not doing its duty? We are at once confronted by the human factor in the problem. The existing educational agencies which will have to bring about better farming will only slowly become effective, and however imperfect they still may be in England, they are mainly so because of the lack of response upon the part of the farmers. The present occupiers of the land do obtain in many cases a very inadequate return from it, but they make some sort of a living and they hold it up against others who, though they want land, cannot be guaranteed to use it any better. Improved farming means more enterprise, more knowledge, often more capital, and the man who can bring these to the business is far rarer than the man who, given a piece of land even of the poorest quality, will knock a living out of it by sheer hard work and doggedness. While, then, there should be no slackening in our efforts to improve the quality of the management of existing land, there is a case for also using every effort to increase the cultivable area; indeed, it is probable that for some time to come the second process will add most to both the agricultural production and the agricultural population.

Let us now consider what are the factors which determine the fertility of the land that is first brought into cultivation and remains the backbone of farming in the old settled countries. Foremost comes rainfall, and the distribution is almost as important as the amount. Winter rain is more valuable than summer, and though cereal-growing is none the worse and may even obtain better results with a rainless summer, stock-raising and the production of fodder crops are the better for a rainfall that is distributed fairly evenly throughout the year. Rainfall, again, must bear some relation to temperature; some of the best farming in the Eastern Counties of England is done on an average rainfall of 20 inches; there are great areas in South Africa with the same average rainfall that are little better than desert. In temperate regions we may say that the naturally fertile land requires a rainfall of from 20 to 50 inches per annum, not too much segregated into seasons, and some at least falling in the winter.

If the rainfall is excessive or the drainage inadequate to carry it off, the formation of peat is induced, resulting in such uncultivated areas as the bogs of Ireland and the moors of Eastern England, Holland, and Germany.

Given suitable rainfall and temperature the texture of the soil becomes a factor of importance; if too coarse and sandy, so little of the rainfall is retained that we get all the effects of drought secondarily produced. In itself the open texture of a coarse, sandy soil is favourable to plant development; under irrigation, or where the situation is such as to result in permanent water a short distance below the surface, fine crops will be produced on sandy soils that would remain almost barren if they only depended upon the rainfall for their water. In Western Europe large areas of heaths and waste land owe their character to the coarse and open texture of the soil. At the opposite extreme we find clays so heavy that their cultivation is unprofitable; such soils, however, will carry grass and are rarely left unoccupied. For example, in the south-east of England there are a few commons, *i.e.*, land which has never been regarded as worth enclosing and bringing into particular ownership, situated on heavy clay land; most of such land is pasture, often of the poorest, or, if at any elevation, has been covered with forest from time immemorial.

One last factor in the soil is of the utmost importance to fertility, and that is the presence of lime—of calcium carbonate, to be more accurate—in quantities sufficient to maintain the soil in a neutral condition. Old as is the knowledge that lime is of value to the soil, we are only now beginning to realise, as investigation into the minute organisms of the soil proceeds, how fundamental is the presence of lime to fertility. A survey of the farming of England or western Europe will show that all the naturally rich soils are either definitely calcareous or contain sufficient calcium carbonate to maintain them in a neutral condition even after many centuries of cultivation. Examples are not lacking where the supply of calcium carbonate by human agency has been the factor in bringing and keeping land in cultivation. I have discussed one such case on the Rothamsted estate, and several others have come under my notice. The amelioration of non-calcareous soils by treatment with chalk or marl from some adjacent source has been a traditional usage in England and the North of France: Pliny reports it as prevailing in Gaul and Britain in his day, and the farmer of to-day often owes the value of his land to his unknown predecessors who continuously chalked or marled the land. Upon the presence of carbonate of lime depends the type of biological reaction that will go on in the soil, the beneficial bacterial processes that prepare the food for plants only take place in a medium with a neutral reaction. The Rothamsted soils have provided two leading cases. I have shown that the accumulation of fertility in grass-land left to itself and neither grazed nor mown, so that virgin conditions were being re-established, was due to the action of the organism called Azotobacter, which fixes free nitrogen from the atmosphere, and was indirectly determined by the presence of calcium carbonate in the soil, without which the Azotobacter cannot function. Examination of typical examples of black soils from all parts of the world, the prairies of North America, the steppes of Russia and the Argentine, New Zealand and Indian soils, showed in all of them the Azotobacter organism and a working proportion of carbonate of lime. Now, as we know, all virgin soils are not rich, and only in a few parts of the world are to be found those wonderful black soils that are often several feet in depth

and contain 10 to 20 per cent. of organic matter and 3 to 5 parts per thousand of nitrogen. These soils are all calcareous, they occur in regions of a moderate rainfall inducing grass-steppe or bush conditions, and the annual fall of vegetation provides the organic matter which the Azotobacter requires as a source of energy in order to fix nitrogen. Non-calcareous soils under similar climatic conditions do not accumulate nitrogen and become rich; in the absence of carbonate of lime the nitrogen-fixing organisms are not active, and the soil only receives from the annual fall of vegetation the nitrogen that was originally taken from it. There is but a cyclic movement of nitrogen from the soil to the plant and back again, whereas in the calcareous soils there is also continuous addition of fresh nitrogen derived from the atmosphere, in which process the carbonaceous part of the annual crop supplies the motive power.

The other leading case to be found at Rothamsted is that of certain grass-plots which have artificially been brought into an acid condition by the continued application of sulphate of ammonia. In these soils nitrification is suspended, the nitrification organisms have even disappeared, though the herbage still obtains nitrogen because most plants are able to utilise ammoniacal nitrogen as well as nitrates. The interesting feature, however, is that the decaying grass on these acid soils passes into the form of peat, a layer of which is forming upon the surface of the soil, though nothing of the kind is found on adjacent plots where the use of lime or of alkaline manures has prevented the development of acidity. From this we may learn that the development of a surface layer of peat, independent of waterlogging (when another kind of peat forms even under alkaline conditions), is determined by the acidity of the soil, when certain of the bacterial processes of decay are replaced by changes due to micro-fungi which do not carry the breaking-down of organic matter to the destructive stage. This affords us a clue to the origin of many areas of upland peat in the British Isles, where the remains of ancient forest roots and stumps of trees are found on the true soil surface below the layer of peat, but where there is no water-logging to bring about the death of the trees and the formation of peat. We may suppose that when the land-surface became fit for vegetation at the close of the glacial epoch it covered itself with a normal vegetation, chiefly dwarf forest, because of the rainfall and temperature. The soil, however, being without carbonate of lime, would in time become acid with the products of decay of the vegetable matter falling to the ground, and as soon as this acid condition was set up peat would begin to form from the grassy surface vegetation. The process would continue until the acid conditions and the depth of the accumulating layer of peat would kill the trees, the stumps of which would remain sealed up below the peat. I am far from thinking that this explanation is complete, but at least we have facts in sight which could lead one to suppose that a non-calcareous soil originally neutral and carrying a normal vegetation can naturally become acid, alter the character of its vegetation, and clothe itself with a layer of peat. The point of economic importance is that these peaty acid soils are of very little value as long as they are acid, though they take on a quite different aspect if they are limed and made neutral.

Of all the soil factors making for fertility I should put lime the first; upon its presence depend both the processes which produce available plant food in quantities adequate for crop-production at a high level and those which naturally regenerate and maintain the resources of the soil; it is, moreover, the factor which is most easily under the control of the agriculturist.

I need say little about those cases in which infertility is due to the presence in the soil of some substance which is actually injurious to plant-growth, because such substances are nearly always due to the physical environment of the soil, to too much or too little water. In waterlogged situations we may find in the soil peaty acids, iron salts, sulphides, etc., inhibiting the growth of plants; in arid regions the soil may still be charged with an excess of soluble compounds of the alkalis and alkaline earths, resulting from the decomposition of the rocks that have been broken down to form the soil, but which through the inadequate rainfall have never been washed out. The establishment of normal conditions of growth, irrigation in one case, drainage in the other, will speedily result in the removal of the deleterious substances. Practically, only bodies that are soluble can get into a plant to injure it, hence such bodies can be removed from the soil by water, provided that the water can find its way through the soil and escape.

Let us now consider the various methods by which land suffering from one or other of the disabilities we have just discussed is nowadays being brought into cultivation. The most important, if we consider the area affected, is the extension of cropping into regions of a deficient rainfall by means of what has been termed dry-farming. So far as its immediate methods go, dry-farming consists in nothing more than the application of the principles of husbandry worked out by English farmers in the east and south-east of England, principles first expounded by Jethro Tull, though a complete explanation was not then possible, even if it is now. In the first place, the tilth must be made both deep and fine, thus whatever rain falls will be absorbed and the conditions favouring a deep and full root range will have been established. Next, the soil below the surface, though finely worked, must be compact, because only thus can the water present travel to the roots of the plant. Lastly, a loose layer must be maintained on the surface, which, though dry itself, acts as a screen and a barrier to prevent loss of water from the effective soil below by any other channel than that of the plant. Granted these methods of cultivation, the new feature about "dry-farming," which has been introduced by settlers in the arid districts of Australia and North America, is the use of a year of bare fallow in which to accumulate a supply of water for the next year's or two years' crop. This raises the fundamental question of how much water is necessary for the growth of an ordinary crop. The first investigation that Lawes and Gilbert carried out at Rothamsted dealt with this very point; they grew the usual field crops in pots, protected the surface of the soil from evaporation so that all the loss of water proceeded through the plant, weighed the water that was supplied from time to time, and finally weighed the produce, expressing their results as a ratio between the dry matter produced and the water transpired by the plant. These experiments have been repeated under different climatic conditions by Hellriegel in Heidelberg, by Wollny in Vienna, by King and others in America. Now the two processes in the plant, carbon assimilation and transpiration, are not causally connected, though, as both are carried out in the leaf and have some factors in common, they are found to show some constancy in their relative magnitudes. Lawes and Gilbert obtained a ratio of about 300 lb. of water transpired for each pound of dry matter harvested, but the other investigators under more arid conditions found much higher figures, up to 500, and even 700 to 1. Now, a crop yielding 20 bushels of wheat per acre will contain about a ton of dry matter per acre, so that, taking the high ratio of 500 to 1,

no more than 500 tons of water per acre or 5 in. of rain will have been consumed in the production of this crop.

It is, of course, impossible to ensure that all the rain falling within a year shall be saved for the crop; much must evaporate before it reaches the subsoil where it can be stored, and only when the crop is in full possession of the land can we expect that all the water leaving the soil shall go through the crop. What proportion the waste bears to that which is utilised will depend not only on the degree of cultivation, but upon the season at which the fall occurs; summer showers, for example, that do not penetrate more than a few inches below the surface will be dissipated without any useful effect. When the climatic conditions result in precipitation during the winter, the water will be in the main available for crop-production; and it has been found by experience that cereals can be profitably grown with as small a rainfall as 12 in. The necessary cultural operations consist in producing such a rough surface as will ensure the water getting into the subsoil; hence autumn ploughing is desirable. Where the precipitation is largely in the form of snow, a broken surface also helps both to absorb the thawing snow and to prevent it being swept into the gullies and hollow places by the wind. On some of the Russian steppes it has become customary to leave a long stubble in order to entangle as much snow as possible, but probably a rough ploughing before the snowfall would be even more effective. When the rainfall drops to the region of 12 to 16 in., and occurs during the summer months, then dry-farming methods and the summer fallow become of the first importance. The deep cultivation ensures that the water gets quickly down to the subsoil away from danger of evaporation, and the immediate renewal of a loose surface tilth is essential in order to conserve what has thus been gained.

In connection with this dry-farming there are several matters that still require investigation before we can decide what is the minimum rainfall on which cultivation can be profitable. In the first place, we are only imperfectly informed as to the relation between rainfall and evaporation. At Rothamsted there are three drain-gauges side by side, the soil layers being 20, 40, and 60 in. deep respectively. The surface is kept rough and free from growth, though scarcely in the condition of looseness that could be described as a soil mulch. Yet the evaporation, even under a moist English atmosphere, amounts to one-half of the annual rainfall, and the significant thing is that the evaporation is approximately the same from all the gauges and is independent of the depth of subsoil within which water is stored. Evaporation then would seem to be determined by surface alone, but we are without systematic experiments to show how variations in the surface induced by cultivation will alter the rate of evaporation. A knowledge of the evaporation factor would then inform us of what proportion of the rainfall reaches the subsoil; we then want to know to what extent it can be recovered, and how far it may sink beyond the reach of the crop. It is commonly supposed that the subsoil below the actual range of the roots of the crop may still return water by capillarity to the higher levels that are being depleted, the deeper subsoil thus acting as a kind of regulating reservoir absorbing rain in times of excess and returning it when the need arises. But some work of Leather's in India and Alway's on the great plains of North America throw doubt on this view, and would suggest that only the layer traversed by roots, say, down to a depth of 6 ft., can supply water to the crop; the water movements from the deeper layers due to capillarity being too slow to be of much effect in the maintenance of the plant. The evidence on either side is far from being conclusive, and more experiment is very desirable.

It would also be valuable to know how far evaporation from the bare soil can be checked by suitable screens or hedges that will break the sweep of the wind across the land. In England hedges have always been looked at from the point of view of shelter from stock; we find them most developed in the grazing districts of the west, while bare, open fields prevail in the east and south. Yet the enormous value of a wind-screen to vegetation can be readily observed, and the market-gardeners both in England and the still dryer districts of the south of France make great use of them. Lastly, we must have more knowledge about the relation between transpiration-water and growth; we do not know if the high ratios we have spoken of hold for all plants. Xerophytic plants are supposed to be possessed of protective devices to reduce loss of water. Are they merely effective in preserving the plant from destruction during the fierce insolation and drying it receives? and do they enable a plant to make more growth on a given amount of water? Wheat, for example, puts on its glaucous, waxy bloom under dry conditions: Is this really accompanied by a lower rate of transpiration per unit surface of leaf? and is it more than defensive, connoting a better utilisation of the water the plant evaporates?

The cultivation of these soils with a minimum rainfall necessitates varieties of plants making a large ratio of dry matter to water transpired, and also with a high ratio between the useful and non-useful parts of the plant. Mr. Beaven has shown that the difference in the yields of various barleys under similar conditions in England are due to differences in their migration factors: the same amount of dry matter is produced by all, but some will convert 50 per cent. and others only 45 per cent. into grain. This migration ratio, as may be seen by the relation between corn and straw on the plots at Rothamsted, is greatly affected by season; nevertheless, Mr. Beaven's work indicates that under parallel conditions it is a congenital characteristic of the variety, and therefore one that can be raised by the efforts of the plant-breeder. The needs of dry-land farming call for special attention on the part of the breeder to these two ratios of transpiration and migration.

Closely linked up with the problems of dry-land farming are those which arise in arid climates from the use of irrigation water on land which is either impregnated with alkaline salts to begin with or develops such a condition after irrigation has been practised for some time. The history of irrigation farming is full of disappointments due to the rise of salts from the subsoil and the subsequent sterility of the land, but the conditions are fully understood, and there is no longer any excuse for the disasters which have overtaken the pioneers of irrigation in almost every country. Sterility may arise from two causes—overmuch water, which brings the water-table so close to the surface that the plants' roots may be asphyxiated, or the accumulation by evaporation of the soluble salts in the surface layer until plants refuse to grow. The annual cutting off of the cotton crop in Egypt as the water-table rises with the advance of the Nile flood affords a good example of asphyxiation, but in the neighbourhood of irrigation canals we also find many examples of sterility due both to the high water-table and an accompanying rise of salts. The governing principle is that drainage must accompany irrigation. Even if free from salts at the outset, the land must accumulate them by the mere evaporation of natural waters, and they will rise to the surface where they exert their worst effect upon vegetation, unless from time to time there is actual washing

through the soil and removal of the water charged with salt. Without drainage the greater the quantity of water used the greater the eventual damage to the soil, for thereby the subsoil water-table carrying the salts is lifted nearer to the surface. With a properly designed irrigation system the danger of salting ought not to occur; there are, however, many tracts of land where the supply of water is too limited to justify an expensive scheme of irrigation channels with corresponding drainage ditches at a lower level.

Take the case of a farmer with some water from an artesian well at his disposal, with perhaps little rainfall, with land subject to alkali, and no considerable natural fall for drainage. If he merely grades the land and waters it, sterility rapidly sets in; the only possibility appears to be to take a comparatively limited area and to cut out drainage ditches or tile drains 4 or 5 ft. below the surface, even if they have to be led into a merely local hollow that can be abandoned to salt. The bed thus established must then be watered at any cost until there is a flow in the drains, after which the surface is immediately cultivated and the crop sown. There should be no further application of water until the crop covers the land, the use of water must be kept to a minimum, and by the ordinary methods of dry cultivation evaporation must be allowed only through the crop, not merely to save water, but to prevent any rise of salt. With a loose surface and wind-breaks to minimise evaporation it has thus proved possible to grow valuable crops even on dangerously alkaline land. Superphosphate and sulphate of ammonia have proved to be useful fertilisers under these conditions; both tend to prevent the reaction of the soil becoming alkaline, and the calcium salts of the superphosphate minimise the injurious effects of the sodium salts that naturally accumulate in the land. On the other hand, nitrate of soda is a dangerous fertiliser. Attempts have been made to reduce the salts in the land by the growth of certain crops which take up a large proportion of mineral matter, but I have not been able to ascertain that much good can be thus effected. Sugar-beet and mangolds do appreciably reduce the salt content, but are scarcely valuable enough to pay for such special cultivation and the limited irrigation water; the best thing appears to be to grow saltbush on the non-irrigated margin of such areas, if only to prevent the efflorescent salts from blowing on to the cultivated portion.

Let us now turn to the problem of land reclamation as it occurs in north-western Europe. There are two main types of land that have hitherto been left waste, the peaty and the sandy areas. Of the peaty areas we can distinguish again between the low-lying moors bordering the lower courses of the great rivers; for example, in England near the mouth of the Trent, and the upland peat-bogs of which Ireland furnishes so many examples. They have these features in common—an excess of water, a deficiency of mineral salts, and, particularly in the upland bogs, a strongly acid reaction; but they possess great potential wealth in their richness in nitrogenous organic matter. It is in Germany and Holland that the methods of bringing into cultivation these moors have been most completely worked out; in Germany, for example, it is estimated that there are about five million acres of moorland of which about 10 per cent. are now under cultivation. The reclamation process must begin by drainage, which may be carried out by open ditches, but is most satisfactorily effected by pipes, despite the greater cost. The water-table must be kept some 3 ft. below the surface. In districts which afford a market for peat, as, for example, on the Teufelsmoor near Bremen, the reclamation often begins by cutting out the peat, the lower layer of firm peat being won, dried, and sold for fuel. The upper spongy peat can be used for litter, but some part at least must be thrown back. Where the burning peat is thus extracted the excavation is in places pushed further until the underlying sand is reached, and enough of this is dug to spread over the reclaimed area to a depth of 4 or 5 in. and mixed by cultivation with the spongy peat. Even when the peat is not removed, pits are often made in order to sand the land, so great an improvement does it effect in the character of the crops. However, sanding is not possible everywhere, and there are great areas under cultivation where the reclamation begins with drainage, followed by the cultivation of the immediate surface without either sanding or the removal of the burning peat, which indeed are impossible over large areas, but are carried out by the owners of small farms little by little. Special tools are required: certain forms of disc-ploughs and harrows give the best results; heavy tools for large scale cultivation by steam or electricity are furnished with broad roller-like wheels; even the horses must wear broad wooden shoes.

The next stage is the manuring, and it has only been the development of the artificial fertiliser industry during the last half-century that has rendered the cultivation of this type of land possible. On the alluvial moors where the ground water has always been alkaline, the peat is rich in calcium and no treatment with lime and marl is necessary (the English fens afford an example of this type of soil), but on the true peat-bogs (Hochmoor of Germany) the manuring must begin with a good dressing of burnt lime, or, better, of marl or ground chalk. For meadows and pastures two tons per acre of lime, or twice as much of carbonate of lime, should be applied; the amounts may be halved for arable land. This must be followed by about 5 to 8 cwt. per acre of basic slag and an equal amount of kainit, which applications should be renewed in the second year, but then diminished in accord with the cropping. However, some phosphoric acid and potash salts must be continuously supplied, with occasional dressings of lime or chalk on the acid peaty areas. These latter also require in their earlier years nitrogenous manures, for the peat is slow to yield up the nitrogen it contains. The fertilisers should be nitrate of soda or lime, never sulphate of ammonia. The whole success of the reclamation depends on the use of these manures, as the peat in a state of nature is almost devoid of both phosphoric acid and potash; on the acid peats, again, normal growth is only possible after a neutral reaction has been attained by the use of lime or marl. With this manuring it is found to be easy to establish a good meadow herbage in a very short space of time; it is not even necessary to get rid of the surface vegetation of Erica and other heath and bog plants. The manure is put on and the surface is worked continuously with disc-harrows and rollers, but never deeply; a seed-mixture containing chiefly red, white, and Alsike clovers, *Lotus uliginosus*, rye-grass, Timothy, and cocksfoot, is sown in the spring and soon succeeds the native vegetation.

It is impossible to say what is the cost of the reclamation of moorland in this fashion; the big expense is the drainage and the construction of roads, both of which are entirely determined by local conditions. But of the value of the process when accomplished there can be no doubt. I have seen a case quoted from the *Ostfriesische Zeitung*, where a piece of moor bought for 75*l*. was reclaimed and sold for 900*l*.; and, best test of all, one may see in places like the Teufelsmoor, near Bremen, families living in comfort on thirty to forty acres of what was once merely wild moor with no productive value.

Of even greater interest in England is the reclama-

tion of heath-land, which has of late years been proceeding apace in Germany. In this category we may include all land which owes its infertility to the coarse grade and low water-retaining power of the particles of which the soil is composed, the soil being at the same time as a rule devoid of carbonate of lime, and covered in consequence with heather and similar calcifuge plants. In England there exist extensive tracts of uncultivated land of this character in close proximity to the considerable populations, but the process of reclaiming such land for agriculture seems to have come to an abrupt conclusion somewhere about 1850, when the developing industries of the country began to offer so much greater returns for capital than agriculture. That land of the kind can be cultivated with success is evident from the mere fact that everywhere prosperous farms may be seen bordering the wastes, possessing soils that are essentially identical with those of the wastes. These were brought under cultivation when labour was cheaper, often without calculation of the cost because the work was done piecemeal at times when the men would otherwise have been idle. Were any strict account to be framed, the reclamation probably did not pay its way for many years, and it has only become possible again because of modern advances in science and machinery. As examples of the type of land, I may instance the Bagshot Sands on which, in north Surrey, in Berkshire and Hampshire, and again in its southern development in the New Forest, lie so many thousands of acres of uncultivated heath. No systematic reclamation has taken place, but everywhere farms have been carved out on this formation, often by the industry of squatters, and within reach of London the vast supplies of town manure which used to be available have converted some of it into fertile land. The crystallisation of common rights into charters for public playgrounds, its growing appreciation for residential purposes, will now always stand in the way of the utilisation of most of the Bagshot Sands for agriculture, but further afield there are many areas of similar character.

The Lower Greensand is perhaps equally discounted by its residential value, but on the Tertiaries of Dorset, the Crag and Glacial Sands of Suffolk and Norfolk—the brak, the Bunter Beds of the midlands, lie many expanses of waste that are convertible into farming land, just as Lincoln Heath and much of the beautifully farmed land of Cheshire have been gained for agriculture within the past century. Equally possible is an attack upon the sandy areas, warrens or links, behind the sand-dunes on many parts of the English and especially the Welsh coasts; not all of them are wanted for golf, and many can be fitted for market-gardening. Of old the only way of dealing with such land was merely to clear it, burn the rubbish, and start upon the ordinary routine of cultivation, but for a long time on such a system the crops will scarcely pay their way from year to year, and the permanent deficiencies of the soil in lime and mineral salts remain unrepaired. In Cheshire the enormous value of marl and bones in such a connection was early recognised; it has been the later discovery of the potash salts that renders reclamation a commercial proposition to-day. The method that is now followed is to begin by clearing the land of shrubs, burning off the roughest of the vegetation, and turning over a shallow layer in the summer, leaving the heathery sod to the killing and disintegrating action of sun and frost until the following spring. The manure is then put on—lime or ground chalk or marl as before, basic slag and kainit, and the sod is worked down to a rough seed-bed on which lupins are sown, to be ploughed in when they reach their flowering stage. The growth of the lupins makes the land, they supply humus to bind the sand together and retain moisture, they draw nitrogen from the atmosphere, and with the phosphoric acid and potash form a complete manure for succeeding crops. Sometimes a second crop of lupins is ploughed in, but usually the land is put immediately to an ordinary rotation of rye, oats, potatoes, and clover. When the heath-land is divided among small tenants in an unreclaimed state cropping often begins without the lupins, the necessary nitrogen being imported by nitrate of soda, but for years the land shows inferior results. Only the tenant can rarely afford to lose the year the lupin crop involves, and so great is the demand for land in Germany that the State finds its preferable to let the tenant reclaim than to reclaim for him, and charge him as rent the cost of the more thorough process.

And now as to the finance of the operation: the reclaiming down to the ploughing in of the lupin crop costs from 5*l.* to 6*l.* an acre, the bare heath costs from 5*l.* to 7*l.* an acre, the reclaimed land after a few years' cultivation would sell at 20*l.* to 30*l.* an acre. Meantime the State has probably made a free grant for drainage, looking to get some interest back in increased taxation; the local authority has also made roads for which the increased rating due to a new agricultural community must be the only return. It is a long-sighted policy which will only find its full justification after many years when the loans have all been paid off and the State has gained a well-established addition to its agricultural land and its productive population. In comparing English with German conditions there are certain differences to be taken into account—in the first place the work of reclamation will be dearer in England because of the higher price of labour, then the land will not be so valuable when won because the higher scale of prices for agricultural products enhances the price of land in Germany. Next, I doubt, in view of the great industrial demand for men in England, if we have the men available who will bring to the land the skill and power of drudgery that I saw being put into these German holdings of thirty to forty acres in their earlier years of low productivity. Moreover, in Germany these heaths are generally bordered by forests, in which the smallholder gets occupation for part of the year while his wife and children keep the farm going. For this, if for no other reason, afforestation and land reclamation and settlement should go on together. But, despite these drawbacks, I am still of opinion that the reclamation of such heath-lands is a sound commercial venture in England, either for a landowner who is thinking of a future rather than of a present return on his capital, or for the State or other public body, wherever the waste land can be acquired for less than 5*l.* an acre. The capitalised value of its present rental rarely approaches that figure, but the barrenest heath is apt to develop the potentialities of a gold-mine when purchase by the State comes in question. The map of England is so written over in detail with boundaries and rights and prescriptions that the path of the would-be reclaimer, who must work on a large scale if he is to work cheaply, can only be slow and devious.

There are other possibilities of winning agricultural land even in England, from the slob land and estuaries, from the clays nowadays too heavy for cultivation; but the problems they present are rather those of engineering than of agricultural science. What I should like in conclusion once more to emphasise is, that the reclamation of heath and peat-land of which I have been speaking—reclamation that in the past could only be imperfectly effected at a great and possibly unremunerative expense of human labour—has now become feasible through the applications of science—the knowledge of the functions of fertilisers, the in-

dustrial developments which have given us basic slag and potash salts, the knowledge of the fertility that can be gained by the growth of leguminous plants. From beginning to end the process of reclamation of moor and heath, as we see it in progress in north-western Europe, is stamped as the product of science and investigation.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Mr. J. T. Saunders, of Christ's College, has been appointed demonstrator in animal morphology, and Mr. J. Gray, of King's College, has been appointed demonstrator in comparative anatomy. Mr. Saunders has received a commission in the Army, but his post will be kept open for him until the end of the war. Mr. J. R. Menon, intercollegiate student, has been nominated to use the University table at the Zoological Station at Naples.

The following forms part of the address of the Vice-Chancellor of the University, Dr. M. R. James, provost of King's College, on his re-election at the beginning of this month:—

"The remembrance of what has been brilliant or sorrowful in the three terms has paled, for the time at least, before the events of the Long Vacation. The University meets in such circumstances as it has never known. We shall be few in number, and perpetually under the strain of a great anxiety. We may be exposed to actual peril: in any case, we must look forward to straitened resources and, what is more, personal sorrows. Yet there is no doubt that we are bound to carry on our work; for by it we can render definite service to the nation. Our part, while we encourage all of our students who are capable of doing so to serve their country, and while we surrender to that service many valued teachers, is to prepare more men—especially in our medical schools—for rendering active help, and to keep alive that fire of 'education, religion, learning, and research' which will in God's good time outburn the flame of war. Let us devote ourselves to making useful men of the new generation. Let us confine our own controversies within the narrowest limits, and be ready if necessary to postpone them altogether. Let our advanced work—however irrelevant it may seem to the needs of the moment—be unremittingly and faithfully pursued.

"I have spoken of the trials which we are bound to anticipate as a consequence of the war. Let me add that we shall be the better able to bear them, not only because we know that our cause is just, but because we know that the University has contributed a worthy share of its sons to champion that cause. Nearly 2000 applications for commissions from our younger graduates and our undergraduates have passed through the hands of the indefatigable committee of the Board of Military Studies; and this number does not include the very large contingent who have applied through other bodies, those who already held commissions at the outbreak of war, those who have enlisted in the ranks of various branches of the service, or those who are giving their help in tending the sick and wounded without enlisting. It is not at this moment possible to compile accurate lists of all who have responded to the great call. I hope, however, that each college will set itself to secure information as to its own members, with a view to the ultimate publication of the roll of honour of the University.

"It is our plain duty to secure that those who have interrupted their University career for the sake of their country shall suffer the least possible amount of disadvantage thereby. Some measures have already been taken with this object, and others will be necessary.

"I shall have, further, to ask for your co-operation in an effort which is being made to enable some of those Belgian students who in the course of their gallant resistance have been deprived of their whole academic equipment, to continue, in our midst, and with the help of our libraries and teaching apparatus, the life of their universities. This is an object which, I am confident, the Senate will feel honoured in supporting."

The next combined examination for fifty-three entrance scholarships and a large number of exhibitions, at Pembroke, Gonville and Caius, Jesus, Christ's, St. John's, and Emmanuel Colleges, will be held on Tuesday, December 1, and following days. Mathematics, classics, natural sciences, and history will be the subjects of examination at all the above-mentioned colleges. A candidate for a scholarship or exhibition at any of the six colleges must not be more than nineteen years of age on October 1, 1914. Forms of application for admission to the examination at the respective colleges may be obtained from the masters of the several colleges.

Mr. H. Patterson, University of Leeds, has been appointed part-time lecturer in physical chemistry at Battersea Polytechnic.

It is stated in *Science* that the medical school of Western Reserve University receives by the will of Mr. Liberty E. Holden a bequest said to be nearly 200,000*l*. The fund is to be known as the Albert Fairchild Holden Foundation, in memory of Mr. Holden's son.

The Earl of Rosebery has made a donation of 1200*l*. to the London School of Economics and Political Science for the endowment of a prize to be awarded annually in the department of railway transport at that school of the University of London.

The Rural Education Conference, which was constituted by the Board of Agriculture and Fisheries and the Board of Education in June, 1910, was appointed for a term of three years. This period having expired, the conference has been reconstituted by the Board of Agriculture and Fisheries under the name of the Agricultural Education Conference. The duty of the conference will be to discuss, and to advise, the Board upon, all questions connected with agricultural education which fall within the province of the Board of Agriculture and Fisheries, and specific questions will, from time to time, be referred by the Board to the conference for consideration. In addition, any member may suggest for discussion questions other than those formally referred to the conference. The Lord Barnard has been appointed chairman of the conference, and Mr. H. L. French (Board of Agriculture and Fisheries, Whitehall Place, S.W.) will act as its secretary.

Detailed information as to the work of the numerous departments among which the varied activities of the University of Leeds are shared is contained in the calendar for 1914–15. In common with other modern universities, Leeds University includes a faculty of technology, and among its staff are to be found professors of engineering, mining, textile industries, tinctorial chemistry, and dyeing, leather industries, coal gas and fuel industries, and agriculture. Students may graduate in applied science as well as in pure science. The University, which is situated in the heart of a mining district possessing some of the deepest and best equipped of modern English collieries, enjoys the cordial support of the owners and managers of mines, who give the department every facility for

instructing its students. The courses in gas engineering and the technology of fuel meet the requirements of students who are preparing for responsible positions either as gas engineers or in fuel and metallurgical industries. In agriculture the instruction has been arranged to meet the requirements of young men who intend to become farmers, land agents, valuers, or teachers of agricultural science. Other examples could be given of the efforts of the University authorities to provide instruction and guidance for all parts of the community in its area and the support which is being given to the University by all sections of society augurs well for its future usefulness.

From Prof. H. S. Carslaw we have received a report, presented to the International Commission, dealing with the teaching of mathematics in Australia, and now published by Angus and Robertson, Sydney, 1914. Up to the present the education in the schools has been mainly influenced by examinations of the "local" type, controlled by the Australian universities. Prof. Carslaw condemns this system, which, of course, tends to lower the educational ideal of the schools to mere examination cramming. A comparison of the syllabuses of these examinations with those now being introduced into the State high schools, and the system of leaving certificates, fully supports what Prof. Carslaw states. The older examinations contain much work that is difficult, useless, and unstimulating, while the new syllabuses are much more practical, interesting, and educationally valuable. Coming next to the universities, we find that the system of combining mathematics and physics in one department still prevails in the newer institutions, and the numbers of students taking mathematics is on the whole distinctly small, having regard of the fact that the subject is compulsory for engineering students. The course in insurance mathematics is a valuable feature of the Melbourne University, and one which we should like to see copied elsewhere and made attractive to candidates for general degrees in arts and science.

The calendar for the present session of the Armstrong College, Newcastle-upon-Tyne, has been received. The college ranks, together with the "Durham colleges," and the College of Medicine, as one of the three constituent units of the University of Durham. The faculties of science and commerce in the University are seated entirely at Armstrong College, in which alone are held the classes and examinations requisite for bachelor degrees in these faculties. In addition to pure science, the college gives instruction in the various branches of engineering, mining, metallurgy, naval architecture, and agricultural science. The agricultural department directs the Northumberland County Agricultural Experimental Station and the Durham County Station for Dairy Research. For the purpose of forestry instruction the college possesses 900 acres of wood, and its zoological equipment includes a laboratory of marine biology. College diplomas in engineering, naval architecture, mining, mine surveying, agriculture, and commerce, are open to students who are unable to take a complete degree course. A list of the various fellowships for research, scholarships, and exhibitions, of which there is a large number, is given in the calendar. We notice that a fellowship of the value of 125*l.*, and two research studentships of the value of 62*l.* 10*s.* each, are offered for competition in June of each year. The holders must engage in advanced study or research to the satisfaction of the council and be graduates of the University of Durham.

A copy of the calendar for 1914–15 of the Manchester Municipal School of Technology has been received. It is arranged in two parts, one dealing with university courses and the other with part-time courses. The school offers systematic training in the principles of science and art as applied to mechanical, electrical, municipal, and sanitary engineering; architecture and the building trades; the chemical industries; the textile industries; and photography and the printing crafts. Its work includes advanced study and research; university courses in the faculty of technology in the Victoria University of Manchester, of which the school is an important constituent; part-time day courses for engineers' and other apprentices whose employers allow them to devote one whole day a week to study; part-time evening courses, involving attendance on three evenings a week for five years; and other part-time classes for advanced study and research, or in preparation for the external degrees of the University of London, or for other purposes. Students who, having passed the matriculation examination or its equivalent, satisfactorily complete a three years' university course in accordance with the regulations, become entitled to the degree of Bachelor of Technical Science. A fourth year's course of advanced study and research prepares such graduates for the higher degree of Master of Technical Science. These degrees give the holders exemption from further examination when desirous of entering certain professions and learned societies, which are enumerated in the calendar. Very full particulars of the equipment, the various courses, and the general arrangements of the school are given in a manner which makes very simple reference by the intending student.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 14.—M. P. Appell in the chair.—A. **Lacroix**: The recent eruption of Ambrym (December, 1913) and the constitution of the lava from this volcano. The lava is of the angitic labradorite type, too poor in olivine to be considered a true basalt. A complete chemical analysis is given.—Kr. **Birkeland** and M. **Skolem**: Calculations of the lines of equal intensity in the zodiacal light.—B. **Jekhowsky**: The eclipse of the sun of August 20–21, 1914. Particulars of observations taken at the Observatory of Montsouris.—Ch. **Vaillant**: The replacement of photographic plates by gelatino-bromide paper in radiography. By the use of a reinforcing screen with exposures of from 4 to 30 seconds good negatives were obtained. The cost is about one-thirtieth of the ordinary plates.—Julien **Loisel**: The monographic representation of the mean direction of the wind.

September 21.—The President announced the death of M. Pérez, correspondant for the section of anatomy.—Maurice **Hamy**: Remarks relating to the construction of an equatorial *coudé*.—Marin **Molliard**: Chemical modifications of plant organs undergoing a true fermentation.

Calcutta.

Asiatic Society of Bengal, September 2.—W. **Ivanow**: The language of the gypsies of Qāināt (in eastern Persia). The gypsies of eastern Persia are a wandering tribe who live exclusively in tents and present signs of their Aryan origin, with Shemitic, Turkish, and even Dravidian admixtures. They seem to be allied to the Jats, the well-known Kshattriya tribe of India, to the Da-Yueti tribe to which Kaniska belongs, and to other kindred tribes. They dress like Persian peasants, and their religion is Islam of the Shia Sect. Their language has lost its original purity and is now about the same as Persian spoken in Qāināt. There are still some genuine gypsy words which are used to

conceal their secrets, but words indicative of abstract ideas are wanting altogether. The paper also deals with many important features of the genuine gypsy language from the points of view of phonetics, morphology, vocabulary, etc.

THE IBO-SPEAKING PEOPLE OF SOUTHERN NIGERIA.

Anthropological Report on Ibo-Speaking Peoples of Nigeria. By N. W. Thomas. Part iv., *Law and Custom of the Ibo of the Asaba District, S. Nigeria.* Pp. vi+208. Price 4s. net. Part v., *Addenda to Ibo-English Dictionary.* Pp. x+184. Price 4s. net. Part vi., *Proverbs, Stories, Tones in Ibo.* Pp. viii+114. Price 4s. net. (London: Harrison and Sons, 1914.)

LATE in the eighteenth century the European nations then most engaged in the slave trade—Britain, Holland, France, and Portugal—became aware that there was a vigorous, muscular race of negroes called the Ibo—a name rendered in English down to the middle of the nineteenth century Eeboe. They fed the slave markets of Benin, and thence made their way to Brazil and the slave markets of Bonny and Calabar. When Richard Lander and his brother John completed the solution of the Niger mystery and descended the Niger from the Busa rapids to the head of its delta, they were captured by a raiding party of Ibos in canoes, and taken to the headquarters of an Ibo king. Here they were ransomed by the Ijō people of Brass (one of the Niger mouths) and thence actually conveyed to the sea-coast, whence they managed to make their way home.

The sufferings of the Lander brothers directed special attention to the Ibo people, especially as Richard Lander's successful demonstration of the Niger outlets immediately led to the dispatch of trading and exploring expeditions to the River Niger, more or less under British Government supervision. For some fifty years afterwards the Ibos alternately encouraged and repelled the attempts of the British to open up the Lower Niger to commerce. They were really not brought under anything like control until the Royal Niger Company established its headquarters at Asaba in the midst of their country, thirty years ago, and it is in the Asaba district to the west of the Lower Niger that Mr. Northcote Thomas has made his chief studies of the Ibo people, especially those set forth in the three volumes under review.

The region of the Lower Niger below the confluence of the Niger and the Benue, and thence to Lagos on one hand, and Old Calabar on the other, is inhabited by principal stocks (1) the Igara-Yoruba-Jekri; (2) the Sobo-Bini (related to No. 1); (3) the Ibo-Efik; (4) the Ijō; and (5) the Akwa. There are also, perhaps, in the region between the Cross River and Opobo, and again between the main stream of the Niger or Nun and the Forcados River, traces of other negro stocks (such as the Aro) as yet isolated in affinities. The affinities of the Ibo with the Efik people of Old Calabar are not at first sight outstanding, but on examination of the two languages it is evident that there is a deep-seated and obvious relationship, and the traditions of the Calabar people would seem to show that some five hundred years ago they were the result of an Ibo invasion of a region populated at that time by a semi-Bantu stock (the Akwa), which even yet extends very near to the Efik settlements of Calabar. The Ibo language istelf is not without suggestions of an ancient connection with the great Central African speech which must have been part parent of the Bantu. But it has closer relationships at the present day with the tongues of the Niger-Benue confluence and with the Yoruba-Bini groups.

In the volumes under review—valuable contributions to African ethnology—Mr. Thomas treats of the language in a few general remarks and also in a supplement to his Ibo Dictionary published a year or so ago. This supplement will be most useful to students of African languages. Though I still disagree with Mr. Thomas on some points in his orthography, I am quite in agreement with him as to the way in which he renders the voice tones which are such an important factor in the pronunciation of Ibo and most of the languages of the Niger delta and of the adjoining districts of Dahomé and Togoland. His definition of these tones in the last part of vol. vi. is an admirable treatment of a very difficult subject, which in the hands of previous writers has been rendered so obscurely as to leave the mind of the philologist, not unacquainted with Ibo at first hand, in a state of despairing puzzlement. Volume or "Part" iv. touches also on the question, but deals more especially with religion and magic, social and political organisation, marriage, criminal law, slavery, civil law, agriculture, and trade. It is packed with interest for African students and for ethnologists in general. Part v. comprises the Addenda to the Ibo-English Dictionary, and Part vi. is a collection of Ibo proverbs and stories followed, as already stated, by an essay on the voice tones of the language, an essay which enables one to realise how much music enters into human speech in these more primitive peoples. Conversation in Ibo is always like the recitative in Italian opera, which may be similarly descended through thousands of years from that deep-seated negroid element in the Mediterranean peoples.

The addenda to the Ibo-English dictionary are deserving of study by those who are making re-

searches into African myths and beliefs. I single out one point for comment. The Ibo name is given of the Spitting-cobra, that African cobra which seldom strikes at man directly with its fangs, but by a muscular compression of the poison-bag ejects the venom through the hollow tooth to a considerable distance, aiming generally at the eyes of the person it is striking. The Spitting-cobra was, I believe, first heard of in South Africa through the Dutch colonists in the eighteenth century, and it was regarded for a long time as a zoological fable. During the last twenty or thirty years, however, the fact that this cobra (*Naja haje,* or more likely *Naja nigricollis*) can and does really eject its venom with deliberate aim was attested by the present writer and by many other African explorers, and is now a proved fact. This spitting snake is credited with another accomplishment, not merely in Iboland, but in the beliefs of the natives of East Africa, of Nyasaland, of the Gaboon, the Congo basin, and the Cameroons. It is said to utter a sound like the crowing of a cock. [I have heard this allegation sometimes made in regard to the Tree-cobras, *Dendraspis.*] In Mr. Thomas's Ibo Dictionary the cock-crowing is attributed to the Spitting-cobra, as it is in some other parts of Tropical Africa. It is, at any rate, a curious coincidence that this story should be told of one or other of the cobras in Africa, independently, and without any possible collusion between the Europeans who record these statements. At the same time, I do not know that proof has been adduced that this or any other snake could utter any cry but a hiss. If, however, it is shown that the native stories are true, and that there is a snake in Africa which crows like a cock, it may be at the base of the old Greek stories of the Basilisk. H. H. JOHNSTON.

AMERICAN LECTURES ON MATHEMATICS.

American Mathematical Society. Colloquium Lectures. Vol. iv., "The Madison Colloquium, 1913." (i.) On Invariants and the Theory of Numbers. By L. E. Dickson. (ii.) Topics in the Theory of Functions of Several Complex Variables. By W. F. Osgood. Pp. iii+iii+110+iii+111–230. (New York: American Mathematical Society, 1914.)

Elementary Theory of Equations. By Prof. L. E. Dickson. Pp. v+184. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 7*s.* 6*d.* net.

THESE works are very different in scope, but may be noticed together as examples of the way in which mathematics is studied in the United States. Prof. Dickson's treatise on the theory of equations is suited for the average university student, and it is interesting to see how an accurate and distinguished mathematician like the author chooses and discusses his topics. He begins with graphics; and here he does what so many fail to do—gives a warning example to show the risk of drawing wrong conclusions from free and easy plotting. Graphical methods are very useful in this theory in connection with such things as Fourier's theorem, Newton's approximation rule, etc.; they are not trustworthy substitutes for calculation when the real roots of a given equation have to be found. Other things dealt with are the elementary theory of cubics and quartics, symmetric functions, separation and calculation of real roots, determinants, systems of linear equations, resultants. The proof of the fundamental theorem for symmetric functions is the proper one: namely, by establishing the one-one correspondence of the highest part of any given symmetric function to that of a definite product of coefficients—not using the theorem about the sums of powers of the roots. The proof that every equation has a root is substantially that of Gauss; this is a rather noteworthy fact. The omission of the Galois theory is quite natural; but we are inclined to regret that the author did not comment on the solutions of the cubic and quartic so as to show their common features, and prepare the way for group-theory.

The same author's lectures in the Madison Colloquium are addressed to experts, and expound what may be called in the first instance a new and amusing mathematical game. Forms and linear transformations are considered, not absolutely, but with reference to an ordinary integral modulus; the result is to change the problem of finding a complete system of covariants and invariants into one of an entirely different character. Connected with this we have a theory of "modular geometry," and in such things as group-study and the study of configurations this seems likely to be of considerable service. The theory is worked out in detail for a quadratic form in m variables to modulus 2.

Prof. Osgood's course is on the very difficult theory of analytical, and in particular algebraic, functions of two or more independent variables. So far as the subject admits, it is an admirably clear and interesting account of the principal results hitherto attained; in particular, those due to E. E. Levi. A remarkable result of recent investigations is to show that a theorem of Weierstrass's about essential singularities is incorrect. It should also be noted how, here and

there, the theory of sets of points comes into the argument. Abundant references are given to original sources, and in every respect this course seems to be an admirable guide for those who feel inclined to explore this very important, though thorny and still undeveloped, field.

CHEMISTRY: PURE AND APPLIED.

(1) *Geschichte der Chemie von den altesten Zeiten bis zur Gegenwart zugleich Einfuhrung in das Studium der Chemie. Vierte Auflage.* By Prof. Ernst von Meyer. Pp. xiv+616. (Leipzig: Veit and Co., 1914.) Price 13 marks.

(2) *Chemistry and its Borderland.* By Dr. A. W. Stewart. Pp. xii+314+11 plates. (London: Longmans, Green and Co., 1914.) Price 5*s.* net.

(3) *Industrial Chemistry for Engineering Students.* By Prof. H. K. Benson. Pp. xiv+431. (New York: Macmillan Co.; London: Macmillan and Co., Ltd., 1913.) Price 8*s.* net.

(1) SINCE the date of the first edition in 1888, Prof. v. Meyer's History of Chemistry has been the fullest account of the progress of the science, and most of the present-day chemists owe much of their knowledge of the work of their predecessors to its perusal. In the earlier editions the work of individual chemists was given under their respective names, and it was difficult for the reader to get a clear idea of the development of chemical theory as a whole. In this respect it was inferior to the shorter histories of Wurtz and Tilden, in which the individual workers are mentioned indeed, but their work forms a continuous narrative. In the later parts of this new edition this defect has been largely removed, but without re-writing the whole book it could never be made into a history from which a student could obtain a clear idea of the way in which our present idea of chemical theory had been arrived at. Historians will undoubtedly differ in their estimate of the importance of the several branches of their subject, and probably no two chemists would agree as to the proportion of attention which should be given to any one branch. For instance, it would seem unnatural to many that only three pages out of six hundred should be devoted to Mendeléeff's periodic classification of the elements, the only great generalisation which binds together the otherwise disconnected facts of inorganic chemistry, and that the important additions which Sir J. J. Thomson (spelt Thomsen) has made to chemical science should be dismissed in two lines.

(2) It is difficult to imagine for what class of readers this book is intended. An attempt to teach the final conclusions of a complicated and difficult science in a book of 300 pages, starting *ab initio,* is foredoomed to failure. To the country clergyman who wishes to keep "abreast with the times" it may do no great harm, but it is to be hoped that it will never be given as a prize to a promising schoolboy. A statement like "Inorganic chemistry now includes the chemistry of all the compounds which do not contain any carbon," may be a slip, but the description of the discovery of argon is an untrue representation of the facts. There is a whole chapter on the transmutation of the elements in which the case for transmutation is stated at great length, while the barest mention is made of experiments on the other side. Collie and Patterson have maintained a most praiseworthy reserve as to the conclusions to be drawn from their experiments, and the author would have done well to imitate their reticence.

(3) Of the importance of a knowledge of chemistry to engineering students no one now has any doubt. All the most eminent engineers when consulted as to the curriculum of an engineering school, have emphasised the absolute necessity of the inclusion of an adequate chemical training. In spite of this at least two universities in this country ignore the subject for their engineering students, partly because the authorities consider that the course is already too extended, and partly because it is sometimes difficult to persuade the students of the importance of knowing the character and properties of the materials with which they will have to work. In the best engineering schools, however, the students have a preliminary course of pure chemistry during their first year, followed in the next year by a course of more technical chemistry as applied to engineering. This consists of three principal divisions: (1) Fuels of all descriptions and their modes of application; (2) metallurgy, including the composition and properties of alloys; (3) water in relation to boiler practice, cements and protective materials and coatings.

Prof. Benson has expanded his lectures to engineering students in the University of Washington into the book under review, and judging from it the young American engineer has a chemical training similar to that given to our own students. It is always a matter of difficulty to make a book from lecture notes, and it must be admitted that this one is not free from the defects which are seen in most other books produced in similar circumstances. Most of the descriptions of plant and apparatus are too brief to indicate the way in which the apparatus works, and in many cases a diagrammatic representation would

have been much more illuminating than reproductions of photographs of the outside of the machines. Apart from this defect, which would be corrected by a good lecturer, we have nothing but praise for the book. The chapters on hydraulic cements are particularly good, and there is also a good description of industrial alloys.

LIFE AND ITS INTERPRETATION.

(1) *Les Inconnus de la Biologie déterministe.* By A. de Gramont Lesparre. Pp. 297. (Paris: Felix Alcan, 1914.) Price 5 frs.

(2) *Einführung in die Tierpsychologie auf experimenteller und ethologischer Grundlage.* By Gustav Kafka. Erster Band. Die Sinne der Wirbellosen. Pp. xii+594. (Leipzig: J. A. Barth, 1914.) Price 18 m.

(3) *L'Espèce et son Serviteur.* (Sexualité, Moralité.) By Prof. A. Cresson. Pp. 347. (Paris: Librairie Felix Alcan, 1913.) Price 6 frs.

(4) *Life and Human Nature.* By Sir Bampfylde Fuller. Pp. xii+339. (London: John Murray, 1914.) Price 9*s.* net.

(5) *Controlled Natural Selection and Value Marking.* By J. C. Mottram. Pp. ix+130. (London: Longmans, Green and Co., 1914.) Price 3*s.* 6*d.* net.

(1) A. DE GRAMONT LESPARRE makes a very eloquent protest against determinist biology which has no use for the soul. He indulges in not a little sarcasm at the expense of those who regard the psychical life as an epiphenomenon of cerebral metabolism, and hold that physics and chemistry are sufficient, or will eventually be sufficient, for the description of an animal's daily life. He considers sensation, memory, heredity, reproduction, instinct, intelligence, and so on, and shows that the way of determinist biology is hard. Instead of clearing things up, it lands us in an intellectual fog. He will not have anything to say to "psychoids" and the like, but stands for the old-fashioned soul, an active intellectual principle, simple and autonomous, existing alongside of or rather above physiological phenomena. It is well that the difficulties in the way of mechanistic interpretation should be firmly pointed out, and the author's passionate eloquence need not be taken amiss in these days of compromise; it is well to point out the dangers of question-begging phrases like "the life of crystals," and "the memory of a twisted thread"; it is also well to proclaim the inestimable value of the concept of personality; but we think it far from well that one of the author's standing should give in the closing pages of his book an account of the present state of the theory of organic evolution which we do not hesitate to call a pessimistic and reactionary misrepresentation.

(2) Dr. Gustav Kafka has done an admirable piece of work in bringing together in a synoptic, rather than encyclopædic manner, what is known in regard to the senses of invertebrates. It is the first volume of an introduction to animal psychology, and it raises our expectations for what is to follow. The book is clear and scholarly, and it does not lose sight of the wood in studying the trees. It deals with touch, equilibration, hearing, sensitiveness to temperature, to chemical influences, and to light; and ends with "space-sense" (as in homing) and "time-sense" (as in rhythmic movements), though the author admits that these two titles are scarcely justifiable psychologically. The book has abundant and interesting illustrations, but some of them are a little rough. There is a useful, well-selected bibliography. As to the author's general position, he believes strongly in physiology and psychology minding their respective businesses. The physiologist has to work at the series of spatial happenings between the stimulus and the reaction; the psychologist has to work out a subjective description. Just as a chemist would not be warranted in postulating a magician because he did not follow some of the steps in a long and complicated series of reactions, so the physiologist must not postulate a psychoid factor in his nexus between stimulus and response. But the psychologist need make no apology for working out a different kind of description, equally necessary, and certainly not less real. He must keep close to the observed facts of behaviour, but in his psychological account of these he need not allow himself to be too much hindered by the difference between the nervous organisation of the lower animal and that which he himself possesses. There may be analogous psychical life though the anatomical architecture is quite different. A snake can move very effectively, though it has no limbs.

(3) The aim of Prof. Cresson's admirable book is to emphasise the extent to which organisms are adapted for securing the welfare of their race. In their multiplication, in their reproductive processes, in their parental care, individuals do much that is not to their own advantage; their personal interests have been subordinated to those of the species. They are borne on by impulses and instincts which are as compelling as hunger and thirst, but apart from sexual gratification (which applies only to a relatively small number of cases) the fulfilment of these impulses and instincts is often of little individual advantage. Indeed,

it is often fatal. As Goethe said, Nature holds that for the pains of a lifetime it is fair payment to get a couple of draughts from the cup of love. But many animals have not even this, or the psychic reward of seeing the offspring for the good of which they more or less unwittingly spend themselves.

The author illustrates the physiological cost of producing germ-cells, of nourishing the young before or after birth, of parturition, and so on. Many females die of reproduction, and the drone-bees are far from being the only males that are sacrificed on the altar of sex. Many animals, notably insects, spend a very large proportion of their energy in securing the safety of the eggs and the nourishment of the young. In a charming way the author reminds us, in reference to birds, of the work of nest-making, the patience of brooding, the self-forgetfulness exhibited in feeding, cleaning, guarding, and educating the young. For social insects the formula is suggested: "Everything for the species; everything by the individual; nothing for the individual."

What difficulties often lie in the way of the fertilisation of the egg-cell! How much time, experimenting, vital energy, and elimination has gone to the establishment of the structural adaptations, the impelling desires, and the subtler psychical devices which secure this end. There are parallel adaptations of body, emotion, instinct, and intelligence, which secure the welfare of the young. The author has done very valuable service in bringing into prominence the amount of energy expended towards the maintenance of the species rather than towards self-preservation and self-gratification. Animals have become interested organically, if not consciously, in working for the species; they do not know it, but their personality completes itself in the larger life of their race. They may sometimes work under an illusion, but many are enriched and many are pleased; they do not wholly lose their reward. Metaphors apart, variations (probably altogether germinal to begin with), in directions which made for the welfare of offspring, family, society, or species, have been established in the course of selection no less securely than those which made for self-preservation. Metaphors again, this has been Nature's way of setting the seal of her approval on altruistic behaviour, even when the animal's left hand certainly does not know what its right hand doeth.

(4) Sir Bampfylde Fuller's well-written and wholesome book is divided into three parts—the attributes of life; the constraining influences of race, environment and culture; and man's achievements, material, intellectual, and social. Though the most valuable part of the book is probably the third, which gives expression to the author's experience as an administrator, we must restrict ourselves here to the more strictly biological discussion.

What life in essence is we do not know; we must make the same confession in regard to electricity and gravity; but we cannot suppose that life is the result of matter. We must judge of life by its manifestations. Thus changefulness is one—the flux of everyday metabolism, the cyclical development of the individual, the prodigal variability which evolution implies. Another prerogative is effectively responsive sensitiveness, differing from that of a photographic plate in being associated with a more or less clear "awareness." The other attributes on which the author lays emphasis are instinct and consciousness, spontaneity and repetitiveness. We do not think that he states the attributes very clearly, but no two people agree about this, and it is perhaps more important that he writes in a fresh and interesting way about them from a frankly vitalistic point of view. Living creatures are better defined by their impulses than by their organs. "We do not see because we have eyes, but we have eyes because we have an impulse to see." Life is not a series of activities produced by a particular type of substance or machinery, but may be better thought of as a complicated energy of (it may be figured) "interlacing whirls which animates the mechanism of the body, and is not caused by it." The author shows no wavering in his conviction that life transcends mechanism.

(5) Dr. Mottram thinks that he has got hold of a new theory, supplementary to Darwinism. He illustrates it with enthusiasm and with a pleasant frankness, most of his test cases being taken from birds. The theory is that of *controlled* Natural Selection, which seems to mean this:—The variations presented to the sieve of Natural Selection are not all of the same value for the welfare of the species; thus variations in males are not so important as variations in females, for males are less valuable than females; and one set of variations is more liable to be selected than another, challenging criticism more, as it were. Thus what Natural Selection effects is in a sense "controlled" by the nature or value of the variations that are forthcoming. What truth is there in this? If we compare the action of Natural Selection to that of a pruning knife, and liken variations to the new growths of a tree, we may say that the final result is a function of the growth on the one hand and the pruning on the other. But the phrase "controlled selection" is surely misleading. Then again, as

to value, some new departures are certainly of more value than others, but the value is relative, not absolute; it is in relation to the particular exigencies of the species. We agree with the author that a variation may be established, though it is not of individual value; thus, as Darwin clearly stated, a variation in the direction of greater parental care may become a race-saving specific character, but its value is always in relation to particular conditions of life, *i.e.* in relation to the selection that goes on. To say that Natural Selection is thus controlled is arguing in a circle.

Dr. Mottram has an excellent chapter on the values of conspicuousness, whether of movement, form, sound, scent or colour; and he has the courage to uphold the thesis—the converse of Wallace's—that "the male becomes brilliant in colour in order that he may be more likely to be destroyed: and thus the dull-coloured female gain protection"! This would naturally lead to the elimination of the more brilliant males, but fortunately they mate before they are killed, so that their brilliant qualities are handed on! It would be equally easy to suggest that the character which is established is not merely conspicuousness, but conspicuousness plus such agility that the gay fellows are never caught. We think that the author should re-consider his theory. As a lover of birds, by the way, he should not have passed such a large number of disfiguring misprints in their proper names—we counted ten without looking for them.

OUR BOOKSHELF.

Clean Water and How to Get It. By Allen Hazen. Second edition, revised and enlarged. Pp. xii + 196 + plates. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 6*s.* 6*d.* net.

WE are glad to see a second edition of Mr. Allen Hazen's useful little book on water purification. There are still the interesting chapters describing the various sources of supply and methods of purification, and considerable space is devoted to the problems arising from the tastes and odours developing in water through stagnation and the growth of organisms. Other chapters relate to statistics of supply in different cities, and suggestions are made as to the relative sizes of the several parts of a water works which would be useful in designing a new supply.

New chapters have been added dealing with the "red water" problem, and with the disinfection of water supplies, and it is unfortunate that, with regard to the latter question the author has not gone into the subject more fully, as it is a question which has recently received a great deal of study, both in this country and more particularly in the United States.

Two omissions immediately occur to the English reader, the first being that the author fails to recognise the pioneer work done in this country by Dr. Houston and others on the use of hypochlorites as sterilising agents, and does not mention at all that the first time these substances were used on any considerable scale was at Lincoln in 1905, when in consequence of a serious epidemic of typhoid fever the whole of the water supply was continuously sterilised with sodium hypochlorite by Dr. Houston for more than a year with remarkable success.

The other point is that no mention whatever is made of the now well-known "excess lime" method of sterilisation of Dr. Houston, which was first described by him in 1912 in his reports to the Metropolitan Water Board, and has since been successfully applied to several water supplies both in this country and in the United States.

The book is well illustrated with photographs, and is worth a place on the bookshelf of everyone engaged in the scientific study of water supply.

D. B. B.

The Vaccination Question in the Light of Modern Experience: An Appeal for Reconsideration. By Dr. C. K. Millard. Pp. xviii + 243. (London: H. K. Lewis, 1914.) Price 6*s.* net.

DR. MILLARD'S book is carefully and well written, and with authority; and the general plan of it is very good. He believes, absolutely and profoundly, in the power of vaccination to safeguard each of us against smallpox; and he is outspoken, as he ought to be, over the folly of all who deny this fact. But he feels, very strongly, that the "Leicester experiment"—the rigorous constant notification, isolation, surveillance of contacts, sanitation, emergency vaccination, and so forth—has been a success, not a failure. He points out, very truly, that the danger is less from severe cases than from slight, "masked," unrecognised cases; and these cases often occur in persons lightly and inadequately vaccinated to satisfy the law. He tells the dreadful story of Dewsbury and of Gloucester, where the people had Leicester's anti-vaccination spirit without Leicester's sanitation. The main purpose of his book is to underline the difference between vaccination as a personal safeguard and vaccination as a civic safeguard.

The whole book is of singular interest. It is open to criticism here and there. The author does not lay enough stress on the fact that evil or fatal effects from non-aseptic vaccination belong, nearly all of them, to a time which is happily over and done with. He does not sufficiently reckon with the chance of contact cases escaping from surveillance and flitting outside the cordon. It may be, also, that he ought to make more allowance for the possible surprise of the disease flaring up with unexpected virulence of type: we must be very careful how we talk of a disease "dying

out." Still, here is a book well worth buying and studying. The illustrations and diagrams are admirable; and Dr. Millard has not only authority, but an excellent style.

Bibliotheca Geographica: Jahresbibliographie der Geographischen Literatur. Edited by Joseph Müller. Band xviii. Jahrgang, 1909 und 1910. Pp. xvii+483. (Berlin: W. H. Kuhl, 1914.)

ASSOCIATED for many years with the name of Prof. Otto Baschin, this excellent publication is as useful as ever under its new editor. In previous issues the "Bibliotheca Geographica" purported to be a bibliography of *all* geographical books and articles that appeared; the current issue is limited only to scientific writings. And the list of them runs to 480 pages! The student will find in the catalogue all manner of books and studies in learned journals bearing on the many-sided problems of geography, not omitting methods of teaching. Turn, for instance, to the section on Austria-Hungary. Books on physical geography, cartography, climatology, mountains, hydrography, biological geography, historical geography, and last, but not least, maps are mentioned. The diligence of the editor deserves all praise, and his book should prove of great use generally, more especially in countries like Russia, of which the language is a sealed book to most. In many cases, immediately after the entry of a particular book, stands a reference to a review of it. Thus, following Mr. A. L. Salmon's "Dorset" in the "Cambridge County Geographies," we have a reference to the *Geographical Journal*, vol. xxxvi., p. 178, where the book is noticed. This additional information is certainly useful. But it does not go far enough. If only we had some indication in these long lists of books of their relative value (even in a very general way) the "Bibliotheca Geographica" would add much to our indebtedness.

Science and the Miller. By J. S. Remington. Pp. 166. (Liverpool: The Northern Publishing Co., 1914.) Price 4*s*. 6*d*. net.

ENGLAND is justly proud of its milling industry, and the advances made in it both on the mechanical and the technical side during the last decade have given the lead both to Europe and America. Our biggest milling concerns are already willing to learn, and there are indications that the smaller miller, too, is prepared to accept the help that applied science will give him. It is essential, however, that his chemist should be of the right type; such, for example, as is portrayed in the work under notice. The chapter on the training of the flour-mill chemist is an admirable statement of what is necessary, whilst the remarks as to the position the employer should take towards the chemist will be applauded by every man of science with works experience.

Later chapters give hints as to the directions in which the chemist can make himself useful in the mill, and from these we would select that on improvers and enrichment processes for special commendation. This question is imperfectly understood, and has formed the point of attacks by ignorant food reformers in the public Press, who would do well to study Mr. Remington's book.

Lengthy sections of the work are devoted to breakfast, invalid and infant foods, and to the more prosaic subject of feeding cakes and offals. The disposal of residues, such as are made into compound cakes, is a most important consideration to both the flour and oil miller, and it is to be regretted that the average farmer does not yet fully understand the many virtues of the scientifically compounded cake.

Impurities of Agricultural Seed, with a Description of Commonly Occurring Weed Seeds and a Guide to Their Identification. By S. T. Parkinson and G. Smith. Pp. 105+xxxviii plates. (London and Ashford (Kent): Headley Bros, n.d.) Price 3*s*. net.

THE authors of this little book express the hope that it will be of practical use to farmers, seedsmen, teachers and students. This hope will, we believe, be fulfilled, but we hold that had the volume been prepared for a less mixed community it would have been more specifically useful. As it is, the first thirty or forty pages are taken up with generalities—so beloved by the present-day teacher—which, if they are included at all, should come as savouries and not as *hors d'oeuvres*. Farmers know well enough that weeds are bad, and if the main object of the authors is to help farmers to judge of a sample of seed, they might well relegate to an appendix their description of the harm done by weeds, and bring into first place the excellent descriptions and illustrations which now occur in the latter half of the book. These descriptions might also be so adjusted as to occur in all cases opposite the photographs.

Discussion of questions on such subjects as national seed-testing stations and State legislation with respect to weeds might, we think, be omitted altogether, and the space saved filled to better purpose by weed-analyses of actual samples of bought-in seeds, by lists of weeds characteristic of different types of soil, and by notes on the respective appearances of new and of old and "treated" seed. In short, if the authors in preparing a second edition will forget the teacher and the student in agricultural colleges, and think of the farmer—the seedsman can look after himself—they will add to the utility of an already useful little book. The more so if they can persuade the publishers to reduce the price to a shilling.

LETTERS TO THE EDITOR.

Enhanced Series and Atomic Models.

IN the Bakerian Lecture, "Series Lines in Spark Spectra," Prof. A. Fowler indicates an explanation on Bohr's theory of enhanced series in which the Rydberg constant is 4N instead of N. It may be of interest to point out how the model atom described

in my paper (*Phil. Mag.*, December, 1913) would be capable of emitting similar series. This atom can be shortly described as a rotating Thomson atom, capable of executing elastic vibrations. If the negative electron is constrained to remain on the surface of a sphere of radius r within the atom (radius a), it will have a frequency ν given by the formula $\nu = A - N(r/a)^2$, where A depends on the boundary conditions, and the homogeneous radiation emitted will be of amount $h\nu$, where h is the quantum constant.

Reasons are given in the paper for showing that if the atom were executing radial vibrations the electron would be imprisoned on a nodal sphere and usually on the smallest nodal sphere of a given mode. Thus if the radii of the nodal spheres were given by the formula $r = a(n/m)$, where n and m are integers ($n < m$), then in the formula for r we take for a series $n=1$ and $m=3, 4, 5, \ldots$ For the enhanced spectra it is only necessary to suppose that the electrons may be on the second nodal sphere of each mode, *i.e.* putting $n=2$.

ARTHUR W. CONWAY.

Theodore Schwann and the University of Louvain.

IT might not be altogether inappropriate at this time when the world of true culture is grieving inconsolably over the destruction of the University of Louvain, to be reminded that the originator of the famous cell-theory, Theodore Schwann (1810–82), was for nine years a professor at that University. To biologists this fact is probably the most interesting association which the mention of Louvain arouses. Schwann went to Louvain as professor of anatomy in 1838, and left it for a chair at Liège in 1847. It was in 1839 that he gave to the world the cell-theory in a treatise, "Microscopical Researches into the Accordance in the Structure and Growth of Animals and Plants," as the title runs in the translation made by Henry Smith in 1847 for the Sydenham Society.

This great generalisation was made public, therefore, while Schwann was in his chair at Louvain. It is perhaps not so well known that after he had been seven years at Liège, he invented a self-contained respiration apparatus in which carbon dioxide was absorbed and oxygen liberated. It was the precursor of the rescue apparatus so much used in coal mines at the present day, for Hales's apparatus (1726) was too crude to have been of any real value.

It is interesting to know now that, through a crime no expiation can ever atone, the University of Louvain is no more than a memory, its name will be associated with one of the most far-reaching generalisations ever made in the nature of living things—the cell-theory of Schwann of Louvain. D. FRASER HARRIS.

Filtering Power of Sand.

To those who wish to repeat the experiments on the filtering power of sand, mentioned by Prof. Trouton at the recent meeting of the British Association, I would strongly recommend a solution of the aniline colour known as "Nachtblau." A strongly coloured solution of this substance passed through Fontainebleau sand issues from it absolutely colourless for a much longer time than does that of potassic permanganate. C. J. WATSON.

The Midland Institute, Birmingham, October 1.

FLIGHT OBSERVATIONS IN INDIA.[1]

VARIOUS theories have been proposed by different writers to account for the fact that birds are able, in certain countries, to remain suspended or even rise in the air without any apparent exertion and without flapping their wings. This action appears to have become known as "soaring flight," notwithstanding the fact that in two English dictionaries now before us the verb "soar" is defined as meaning to rise in the air, without any reference to the means adopted. On the other hand, the action in question does not necessarily imply rising, but it may exist equally when a bird maintains the same level for an indefinite time. We prefer to describe this action as "sailing flight."

Now while writers innumerable have attempted to offer explanations of this apparently paradoxical phenomenon, very little has been done to obtain systematic records, extending over long periods, of the conditions under which soaring or sailing flight takes place. This is probably due to the fact that in northern Europe, where most scientific work is done, sailing flight rarely occurs. During his residence at Agra, Dr. Hankin has had specially favourable opportunities for observing large birds in sailing flight, and his present record of observations should do much to systematise our knowledge of the subject.

The principal birds which figure in Dr. Hankin's observations are as follows:—

	Span in feet.	Load in lb. per square foot
Cheel (*Milvus govinda*)	4	0·55
Scavenger (*Neophron gingianus*)	5	0·87
Common Vulture (*Pseudogyps bengalensis*)	7	1·13
Black Vulture (*Otogyps calvus*)	6·5	1·23
Adjutant (*Leptoptilus dubius*) ...	9–11	1·54

Dr. Hankin distinguishes a number of different sailing actions, some of them continuous, others alternating with flappings of the wings. These he designates by such names as ease circling, flap circling, flap gliding, flex gliding. A large portion of the book is occupied with illustrated descriptions of the positions of the wings, tail, and body in different kinds of flapping and sailing flight (*cf.* Figs. 1, 2, 3).

The principal theories that have hitherto been advanced attribute sailing flight to irregularities in wind velocity (*cf.* Langley's "Internal Work of the Wind") or upward air currents (Maxim and others). Dr. Hankin attempts to prove that neither of these causes is sufficient to account for the phenomena as they occur in India, and that the explanation must be sought in some other unknown cause. In particular he uses the term "soarability" to designate the state of the atmosphere when sailing flight is possible, and so far as his observations tend to define when and under what conditions this state exists, they constitute a first step in the solution of the problem.

Now Dr. Hankin observes that in fine weather there is a definite time in the morning, varying

[1] "Animal Flight," a Record of Observation. By Dr. E. H. Hankin. Pp. 405—Index. (London: Iliffe and Sons, Ltd., n.d.) Price 12s. 6d. net.

from day to day, at which sailing flight commences. Unfortunately, however, he gives very few observations as to the time when it ceases, and in this connection further records are needed. It would be very much more conclusive if he had plotted curves showing the number of sailing birds of different kinds observed during different hours of the day, in the same way that examiners plot curves showing the number of candidates who gain different percentages of marks. In any case, he has fully established the fact that "soarability" commences at a time when the sun's rays are beginning to warm the earth. Furthermore, the sailing flight of these large birds only occurs at a certain height above the ground, which is greater the heavier the bird. In the case of circling flight there is not much difficulty in attributing the effect to localised upward convection currents. Such currents would naturally start at a definite instant, when the equilibrium of the atmosphere had become unstable owing to the heating and consequent expansion of the lower layers. But Dr. Hankin considers that this explanation is not able to account for a certain form of sailing flight which he describes as "flex gliding" (*cf.* Fig. 4).

FIG. 1.—Outline of a cheel curling.

FIG. 2.—Outline of a cheel with wings slightly flexed, as seen in flex-gliding at low speed.

FIG. 3.—Outline of a cheel with wings strongly flexed, as occurs in fast flex-gliding. From "Animal Flight."

The peculiarity of flex gliding is that the bird glides uniformly in a straight line without loss of height, and that a number of vultures may be seen simultaneously flex gliding in different directions. If the energy required were supplied by *localised* air currents, these would affect the motion or the positions of the wings, and Dr. Hankin finds that this is not always the case.

But it must not be forgotten that the expansion of the lower layers of the atmosphere caused by the sun's heat necessarily tends to lift the upper layers as a whole, so that, apart from all convection currents, there must be a general upward movement which increases with the altitude, even though there is not a breath of wind at the surface of the earth. A bird gliding downwards with a *relative* velocity of which the vertical component is equal to that of the ascending air would perform a horizontal flex glide.

From a purely qualitative point of view this explanation exactly fits the circumstances of the case. The cause must necessarily exist under exactly the conditions under which the effects have been observed. The only question is whether the upward motion is sufficient.

Without specifically considering this particular kind of upward motion, one of Dr. Hankin's main objections to any hypothesis of the kind appears to be based on his observation that in fast flex-gliding the quill feathers are bent forward, and that in order to bend them a considerable force, sometimes amounting to 150 grams on a single quill, is necessary. For this reason Dr. Hankin asserts that "sun energy" must be capable of producing a pressure on the wings determined by this force. But he does not adequately discuss the conditions of equilibrium, which require that, for uniform motion, the forward pressure on the wings must be balanced by an equally large head resistance. It is futile to try to explain the action on the wings without accounting for the equal and opposite reactions on the bird's body.

The attempts which Dr. Hankin makes to deal with these statical and dynamical considerations cannot be regarded as altogether satisfactory. In the preface he claims to have avoided the use of technical terms. So, indeed, have many other writers of books on flight, but the mistake is when they substitute something far worse. This book contains several instances of the misuse of the principles and nomenclature of theoretical mechanics. For example, on p. 208 the author finds that there are four chief forces acting on a bird commencing gliding, namely, the pull, the drag, the lift, and the weight, and he says: "The pull consists of the momentum of the bird. This acts in a horizontal direction at the centre of gravity." On the next page he makes the drag and this momentum form a couple "that tends to rotate the bird upwards round its transverse axis—in other words that tends to maintain the angle of incidence." Such an unbalanced couple would increase, not maintain, the angle of incidence, as he himself shows elsewhere.

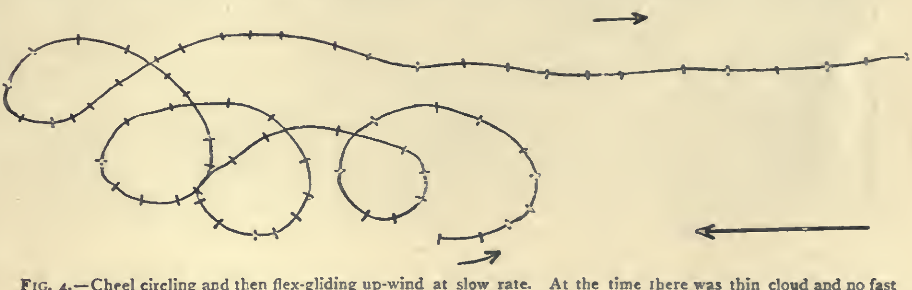

FIG. 4.—Cheel circling and then flex-gliding up-wind at slow rate. At the time there was thin cloud and no fast flex-gliding had occurred. A few minutes later as cloud got thinner, fast flex-gliding of cheels began. Track marked at 1 sec. intervals. Wind at the time not strong enough to move leaves. From "Animal Flight."

Not contented with confusing momentum and force, the author says, on p. 206, "Thus we have arrived at the conclusion that in flex gliding the sun energy stored in the air acts as a constant force."

It is also a pity that the known term "instability" is used to denote rotations which he evidently considers are often due to atmospheric

disturbances rather than to the wings being held in an inherently unstable position. In any case, these rotations could certainly be described as lateral, longitudinal, and directional better than by the suggested names of lateral, transverse-axis, and dorso-ventral axis instability.

However, it must be remembered that this book only claims to be "a record of observations." Dr. Hankin has clearly established the fact, whatever be the explanation, that "sun soarability" must depend on peculiar meteorological conditions which do not exist in temperate climates. As a number of chairs of physics have recently been filled in Indian universities, we may hope that some of the recipients may investigate these conditions, and we must not forget that Dr. Hankin's observations have mainly referred to the *birds* rather than to the *medium* in which they sail.

Further, he has not by any means restricted his attention to the large Indian sailing birds of prey. Gulls, dragon-flies, flying fishes, all come within the scope of his observations, and not the least interesting feature is the difference in action between different species of dragon-fly. That aeroplanes require a greater degree of camber for low than high velocities is a well-known and obvious truth, and the observation that birds can adjust the camber to the speed is highly interesting.

In one chapter are described certain remarkable colour-phenomena noticed in sailing flight. It is, of course, very difficult to judge of such matters by reading descriptions, but it may be safe to refer to similar colour effects which were shown some years ago in "Benham's Artificial Spectrum Top." This consisted of black and white discs with black bands on them, and was exhibited at Cambridge about the time that Dr. Hankin was a Fellow of St. John's.

In conclusion, this "record of observations" forms a worthy sequel to the works of Pettigrew, Marey, and other previous writers. G. H. B.

THE ANTIQUITY OF MAN IN EUROPE.[1]

AMONGST the many services which Dr. Robert Munro has rendered to anthropology during a long and strenuous career, the appearance of this work by Prof. James Geikie is not the least. Dr. Munro founded a lectureship on anthropology and prehistoric archæology in the University of Edinburgh, which Prof. James Geikie was invited to fill. In this book the Munro lectures, containing the ripe experience of the foremost student of the "Ice-age," are placed at the disposal of archæologists and anthropologists all the world over.

It is said that British men of science are inclined

Photo. *Photochrom. Co., Ltd.*

The Lauterbrunnental, Switzerland. B, B, Bottom of Preglacial Valley; O, Trench excavated by Glacier-ice. From "The Antiquity of Man in Europe."

1 "The Antiquity of Man in Europe: being the Munro Lectures, 1913." By Prof. James Geikie. Pp. xx+328+xxi plates. (Edinburgh: Oliver and Boyd; London: Gurney and Jackson, 1914.) Price 10s. 6d. net.

to accept discoveries and classifications made abroad more readily than those made at home. The terms at present employed in British archæological works relating to the phases of the Ice-age certainly might be cited in support of this contention. In 1894, when preparing the third edition of the "Great Ice Age"—of which the work under review may be regarded in some respects as a fourth edition—Prof. Geikie recognised four phases of glaciation, which he named: (1) Scanian, (2) Saxonian, (3) Polonian, (4) Mecklenburgian. British students of ancient man have never adopted these terms; they prefer those which Prof. Penck introduced nine years later—in 1903—(1) Günzien, (2) Mindelien, (3) Rissien, (4) Würmien. Geikie's terms were founded on a study of the glacial deposits of Europe generally; Penck's were the result of a study of glacial deposits in Alpine regions. If priority is to count the British terms have much to commend them. In the present work Prof. Geikie correlates the two systems of nomenclature—the "Scanian" corresponding to the "Günzien," the "Saxonian" to the "Mindelien," the "Polonian" to the "Rissien," and the "Mecklenburgian" to the "Würmien."

In charting the glacial phases of the Pleistocene period, Prof. Geikie and Prof. Penck have provided students of ancient man with an invaluable series of milestones to guide them into that period which is supposed to cover the evolution of modern man. The Heidelberg mandible is regarded by Prof. Geikie as the oldest human remains yet found on the Continent of Europe, and is assigned by him to the interval between the first and second periods of glaciation. He is not fully convinced that eoliths and sub-crag implements are really of human workmanship.

One of the most important contributions made by Prof. Geikie to our knowledge of ancient man refers to the Neolithic period. In the formations and deposits of that time Scotland is particularly rich. From a study of these he has divided the Neolithic period into four phases: (1) lower "forrestian," (2) lower "turbarian," (3) upper "forrestian," (4) upper "turbarian." Each of these phases is marked by a change of climate, a change of flora, and an alteration in the relationship of land and sea. The human remains and objects of culture found in the caves at Oban, usually ascribed to the transitional stage, between the Palæolithic and Neolithic periods, are regarded by Prof. Geikie as belonging to the late Neolithic phase, named up him upper "turbarian."

Prof. Geikie has never indulged in, or countenanced, wild speculation. It is therefore of interest to note the estimate he has formed of the duration of the Pleistocene period. After forty years of study, largely devoted to an examination of glacial deposits, he is of opinion that an allowance of at least 600,000 years must be made for the duration of the Pleistocene period. Man's presence in Europe may, in his opinion, be regarded as extending over a period of 250,000 or perhaps 500,000 years. A. K.

THE CULTIVATION OF MEDICINAL PLANTS IN ENGLAND.

THE question has been asked whether the conditions created by the war in Europe has made it desirable to give attention to the cultivation of medicinal plants in England. The answer is a decided affirmative, but some qualification is needed. Cultivated drugs can never compete with those from wild plants if price prevails over all other considerations. It was only fine appearance and high reputation for therapeutic activity which enabled English aconite, belladonna, digitalis, and henbane to command four times the price of the imported drugs. As it was, severe competition had of late years restricted the use of home produce more and more until it attained relatively small limits.

Much care and skill are needed in preparing the finest qualities of drugs for market, and only comparatively high prices repay this initial trouble and expense. Again, there is only a limited outlet for drugs in general, so that the market is easily overloaded, and when this occurs the highest grades often suffer most as regards depreciation in value. For example, the supply of English-grown belladonna leaves began to exceed the demand in about the year 1900, and a few years ago they were selling in competition with wild Continental drugs—at less than cost. Acreage under belladonna naturally shrank, and, in fact, its cultivation became restricted to a few "materia medica," or drug farms, connected with factories for making extract. Similar experiences led to the cultivation in England of all but a few medicinal plants (*e.g.* valerian, poppy, and dill) being controlled by four firms growing only sufficient for their own requirements. Two successive wet winters, causing excessive loss of plants, had made this season's crops insufficient for normal demands, and the onset of hostilities quickly raised prices to famine rates. High prices restrict usage and stimulate new sources of production until prices become normal again. Both these factors are at work now war in Europe threatens to last for a considerable period, and the first in the field of drug cultivation are likely to reap a profitable harvest.

The writer gave details of cultivation of various drugs in the Journal of the Board of Agriculture for September. Within a week an advertisement in the druggist's trade paper "wanted fertile seeds of belladonna, digitalis, henbane, stramonium; also live roots chamomile, coltsfoot, valerian, spearmint." This illustrates a great initial difficulty, that of obtaining a supply of dormant plants or seeds.

British medicinal plants fall into four categories:—

(1) Drugs which have long been cultivated in this country, but were gradually being ousted by foreign wild products, viz. belladonna, henbane, aconite, digitalis, and valerian. All these, except aconite, are now in great demand. Chamomile (of recent years practically grown only for distillation of oil from flowers) are now almost unob-

tainable owing to Belgian supplies being cut off. Of other aromatic plants grown for distilling purposes, peppermint is not likely to be affected, but spearmint and probably lavender will be dearer. Efforts to extend drug growing will centre around belladonna, henbane, valerian, and chamomile. The first year's returns as regard size of crops will be small, but they will increase rapidly afterwards if remunerative prices are maintained.

(2) Medicinal plants which held their own in competition with foreign supplies:—Dandelion, dill, white poppy, and red poppy petals. Of these the first and last grow wild. The second is as easily grown by farmers as cereal crops. Poppy-head production is a special industry in Lincolnshire. Many of the "botanical herbs" sold by medical herbalists are grown at Carshalton, Surrey, but not in sufficient quantities to supply all home requirements. There is undoubtedly much greater scope at present for the cultivation of medicinal plants in this category. Culinary herbs (marjoram, sage, thyme, etc.) are also worthy of attention.

(3) Plants which grow wild, but are not collected in quantity in this country under normal conditions:—Barberry bark, bittersweet, broom, buckthorn berries and bark, colchicum, coltsfoot, conium, elder flowers and leaves, male fern, rose petals, sweet flag, and yarrow. Considerable sums could be made by organised collection of these (and also of wild dandelion root and digitalis leaves). The most promising from a money-making point of view is male fern rhizome, of which large quantities are needed at once. There is plenty in many localities to be had for the gathering.

(4) Medicinal plants rarely cultivated in this country, but worthy of more attention:—Golden seal, fennel, and thornapple. The last two are easily grown, and in much demand now. The first-named promises rich reward to the successful experimenter.

FIG. 1.—A plantation of English Valerian (*Valeriana officinalis*, L.). From the Journal of the Board of Agriculture, By permission of H.M. Stationery Office.

Most medicinal plants belong to the category of weeds, so that they are not difficult to raise if the ground is kept free from other growths. It is the need for having some facilities for drying leaves and roots that may prevent medicinal herbs being grown by cultivators of other crops as a paying side-line. Medicinal leaves are valued solely by appearance, this being brighter the more

quickly they are dried. In the case of potent drugs, such as belladonna and digitalis, it is imperative that the leaves do not become "heated," this being prevented by spreading in very thin layers. Large growers of drug products have proper drying plant, but a heated glasshouse could be readily converted into a drying shed.

The labour problem is another great hindrance to cheap supplies of British-grown medicinal plants. On the Continent wild plants are collected at odd times usually when harvesting is over. On English drying farms the crops are taken when plants are at their best, the time of collection having in some cases an important influence on the therapeutic effect of the drug. This point is fully recognised in the theory of medicine, but in practice it is usually lost in the modern craze for "cheapness." The cheeseparing policy at times defeats its own object, as the proportion of actual drug in a dose of medicine is so small that doubling the cost of crude drugs would make little or no difference in ultimate cost. A ten-minim dose of digitalis tincture from British-grown drug costs 1/500th penny more than that from imported drug, quite a negligible quantity in comparison with the greater certainty of action.

Fig. 2.—Cutting English belladonna. (*Atropa belladonna*) From the Journal of the Board of Agriculture. By permission of H.M. Stationery Office.

The drug trade is likely to regret bitterly for some time to come the policy which led to the virtual exclusion of home-grown drugs. A considerable extension of the acreage under medicinal plants will result from the conditions created by the European war. When this is over and foreign supplies are again available it is to be hoped that druggists, wholesale and retail, will give that moral and patriotic support needed to prevent it again relapsing.

W. A. Whatmough.

THE BRITISH ASSOCIATION IN NEW SOUTH WALES.

Sydney, August 27.

These lines are written a few hours after the departure of our visitors for Brisbane, where two addresses will mark the conclusion of the first Australian Meeting of the British Association. When the shadow of this cloud of war has passed away, the Australian Meeting will stand out as a notable one. Its total of 4700 members is about 1000 greater than that of any other meeting. Much solid work has been done in the various sections, while great public interest has been aroused by the lectures and addresses. Those who believed that the outbreak of war would have a serious effect upon it have learned that their fears were groundless. Though the minds of all have been filled with anxious thoughts of what may be happening to our soldiers and sailors far away in this crisis of the Empire's fortunes, on all hands there is ample evidence that the meeting has been an unqualified success.

On Thursday, August 20, our visitors arrived from Melbourne, about 10 a.m., in three special trains, and the arrangements for their speedy transit to the houses of their hosts worked admirably. Early in the afternoon the Reception Room at the University began to be thronged with members inquiring for their various tickets, and anxious to secure places in the excursions without delay, which had been arranged for the week-end.

The President delivered the second half of his

address in the Town Hall that evening. With a more than considerate regard to the traditional, if somewhat mythical, rivalry between Melbourne and Sydney, Prof. Bateson had divided his address into two equal parts, and the Sydney members had the privilege of listening to that half in which he discussed problems of heredity more especially as affecting man. The importance of the occasion was marked by the presence in the chair of the Governor, and the Lieutenant-Governor proposed the vote of thanks which followed the lecture. Probably to many in the large audience the literary beauty of the address was as remarkable as the startling statements with which it was punctuated; while Sir Edward Schäfer, in seconding the vote of thanks, gave it as his opinion that we had listened to a deliverance which was epoch-making.

On Friday morning the meetings of the sections were resumed, and the remaining sectional presidential addresses delivered. The presence of Sir Oliver Lodge and Sir Ernest Rutherford attracted large audiences to the Mathematical and Physical Section throughout the meeting. The Geological Section was popular, especially on the last day of the meeting when Sir Douglas Mawson, who had just returned to Australia in time to be present, opened the discussion on Antarctica. The section of Anthropology had most carefully stage-managed the production of the Darling Downs Skull. This discovery, and the presence of Prof. Elliot Smith, Prof. von Luschan, and other anthropologists, attracted large audiences to Section H. And, finally, it is scarcely necessary to remark that, under Prof. Perry's guidance, the meetings of the Educational Section were both lively and well-attended. But so much was heard of the tyranny of the ancient languages that it is whispered that at least one educational authority thought that the time had come for a sub-division of Section L, in order that the friends of Latin and Greek and the Humanities might have an opportunity in calmer surroundings of attempting to solve educational problems in their own way.

I have already spoken of the impression made by the President's address. The two evening discourses were given by Prof. Elliot Smith and Sir Ernest Rutherford. The former was back among his own people; and the huge audience which listened to his address showed that his countrymen were proud of him and of his work. In discoursing on Primitive Man on Friday, he gave special prominence to the discovery of the Darling Downs Skull, announced to the Anthropology Section that morning, by Profs. David and Wilson. It seems probable that this event alone would be sufficient to make the Australian meeting memorable. The second discourse was delivered by Sir Ernest Rutherford in the beginning of the week, also to a large audience. He chose as his subject Atoms and Electrons. Sir Ernest Rutherford, also, was back among his own people, for though the New Zealander is not an Australian, both are Australasians; and it was remarkably appropriate that the honour of giving these two discourses should have been awarded to these two men.

The Citizens' Lectures were delivered under the auspices of the Workers' Educational Association; the first, by Prof. Benjamin Moore, on the Saturday evening. He dealt more particularly with the principles of evolution, both in things organic and inorganic. After demonstrating the operation of bright sunshine on brown earth, he described how the process of evolution is everywhere at work, transforming both nature and society. Prof. Turner, on the Tuesday evening, spoke upon Comets to an audience of more than 3000 people. By accident—or it may have been by design—both these speakers proved to be hearty supporters of the Workers' Educational Association, and the audiences fully appreciated their cordial references to this movement.

The luncheon, which the State Government gave in honour of the Association on Friday, was a most interesting function. The oration by the Premier and the reply by the President of the Association were most remarkable deliverances. The other social events of the week were the garden party at Government House, an afternoon excursion in the Harbour, and the Lord Mayor's ball. There was some talk of this last function being changed into a reception, owing to the special circumstances of the meeting, but to those with whom the decision lay it seemed best that the original programme be carried out. There can be no doubt that all these events added greatly to the enjoyment of the members. Elaborate preparations had also been made for a conversazione at the University on Tuesday evening, at which degrees were to be conferred on some of our distinguished visitors. However, owing to the death on the previous day of the Chancellor of the University, the Hon. Sir Normand MacLaurin, one of the greatest men whom this country has produced, this function was cancelled. The degrees will be conferred *in absentia*.

The excursions arranged for the week-end proved most successful. The members were scattered over a wide range of country. Some, interested in agriculture, were shown what was being done under varied conditions in different parts of New South Wales. Geologists were taken over the coal fields of the Lower Hunter. Engineers visited the Burrinjuck Dam and the Murrumbidgee irrigation area. Botanists saw something of our flora, and zoologists had a successful dredging expedition, while the men of science as a body seemed wholly unable to resist the temptation of the excursions to the Jenolan Caves and the Blue Mountains. These proved so popular that they had to be duplicated.

The British Association has shown its appreciation of the Australian attitude to the meeting in a very practical form. Thanks to the large membership, the sum available for scientific grants is much greater than usual. A large part of this money has been allotted to the Local Com-

mittees, which have been appointed, in almost all the sections, to superintend Australian investigations. It is particularly gratifying to Australians that the Mawson Expedition has received special recognition, and that a grant has been given in aid of the production of the charts of Antarctic sea-depths, founded upon the observations of its members.

The good work done by members of the Association has not been confined to the official meetings. On the evening of their arrival, the astronomers met the local branch of the Astronomical Association; and the Astronomer-Royal and Prof. Turner gave up Sunday to visit in his home, some forty miles from Sydney, Mr. Tebbutt, the well-known Australian astronomer, whose advanced years prevented his attendance at Sydney. On Friday evening, Prof. Gonner and other economists and sociologists met with the local students of these subjects. On Saturday evening, Prof. Perry and Prof. Turner attended a special meeting of the local branch of the Mathematical Association, and by their addresses did a notable service to the teachers of mathematics in the secondary schools. On Sunday, one of the largest halls in the city was packed with an audience eager to hear Sir Oliver Lodge. Finally, the President of the Association filled up the vacancy created by the abandonment of the conversazione, by delivering an address in the Lecture Room of the Geological Department, when he showed a number of slides illustrating the first half of his presidential address, given in Melbourne. Thus, from the beginning of the meeting until its close the personality of its President was felt and realised.

H. S. CARSLAW.

NOTES.

SIR J. J. THOMSON, O.M., F.R.S., will deliver his presidential address to the Physical Society of London at the first meeting of the society, on Friday, October 23. The subject of the address will be "Ionisation," and the meeting will be held at the Imperial College of Science, South Kensington.

THE opening meeting of the new session of the Institution of Electrical Engineers will be held on Thursday, October 29, when the president, Sir John Snell, will deliver his inaugural address. At this meeting a marble bust of Michael Faraday will be presented to the institution by Mr. Llewellyn Preece, on behalf of the family of the late Sir William Preece, past president.

IN connection with the London County Council's work of indicating the houses in London which have been the residences of distinguished individuals, tablets have recently been erected commemorating the residence of Benjamin Franklin, at 36 Craven Street, and of the brothers Adam, at 4 Adelphi Terrace.

Engineering for October 9 has an article commenting on a paper by Mr. C. C. Humphris, of the Barrow Association of Engineers, and dealing with the development of the military small arm. Many charges of the use of unfair bullets have been made on both sides during the present campaign. The old Snider weapon made very bad wounds, but the penetrative power of the bullet sems to have been very small. With the Martini and the original Lee-Enfield bullet very clean wounds resulted. Mr. Humphris states that this is not the case with the new pointed bullet introduced by the Germans, which, unless it hits absolutely perpendicularly to the surface struck, is liable to turn round and proceed flat-long. He showed at the meeting of the association a block of oak fired at by Mark VI. and by Mark VII. ammunition, the latter having the new pointed bullet. The former made a clean hole 30 in. deep, while the latter turned round after entering the block, leaving a lacerated hole. According to Mr. Roosevelt, the tendency for the sharp-pointed bullet to turn in this way is only notable at short ranges.

THE *Engineer* for October 9 has a leading article on engineers and the sugar supply. It is estimated that to produce 1,500,000 tons of sugar would require some nine million tons of beet to be grown in this country. This would require, roughly, one million acres of land to be devoted to beet at one time. Beet should not be planted more often than once in three years—wheat and oats can be cultivated on the same land during the other two years. On the agricultural side, the idea of Great Britain being largely self-supporting as regards sugar is by no means chimerical. The machinery necessary for beet sugar factories can all be manufactured in this country—many of our makers produce it already. To meet the needs of manufacture, 110 factories are suggested, each dealing with 1000 tons of beet a day. Each factory would treat 80,000 tons of beet during its season of eighty days, and would deal with the produce of 8000 acres. The capital outlay on each factory would be about 120,000*l*., and a profit of one-tenth penny per pound of sugar would give a return of about 10 per cent.—notwithstanding the fact that the factory would lie idle during the greater part of the year. The proposal seems to offer large commercial possibilities.

THE interest shown by the Americans in the exploitation of the resources of Peru is shown by the report of Mr. Osgood Hardy, reprinted from the Bulletin of the American Geographical Society, on the industrial prospects of South Central Peru, including the departments of Cuzco and Apurimac. The mineral resources of the district have been only imperfectly explored, and though some mines of silver and copper have been experimentally worked, the result has hitherto been inconsiderable. Above 12,000 ft. the potato is cultivated in a rude fashion, while at lower levels wheat, barley, and maize are grown. The district has recently been opened up by the railway to Cuzco, but the conditions of climate and labour supply are not promising, and the level of agriculture is so low that much demand for modern machinery is not to be anticipated. But so far as the resources of the native population go, some trade in cotton goods, tinned foods, cheap hardware, paints and oils, patent medicines, and toilet articles is being gradually developed.

Dr. Hiram Bingham, director of the Yale Peruvian Expedition, has issued two pamphlets reprinted from the bulletin of the American Geographical Society (vol. xlvi) and *Harper's Magazine* (August, 1914), describing his discovery of a mass of Inca ruins at Espiritu Pampa, Pampaconas Valley, lat. 12° 55′ long. 73° 24′. The district in which this city stood is at present occupied by a very primitive race, the Campa Indians, of whom some account with photographs is given. No other Inca ruins have hitherto been found so low down on the jungles of the Amazon valley. In the Relacion of Diego Rodriguez de Figueroa he describes meeting the Inca Titu Cusi Yupanqui in this neighbourhood, where possibly this was one of his royal cities. While the pottery and architecture are unquestionably of the Inca period it is curious to note that some Spanish roofing tiles were found. It is supposed that these may have been made experimentally by recent Peruvian occupants of the site, or possibly by some early Spanish missionaries who may have come here some three centuries ago.

The Secretary of the Franklin Institute of the State of Pennsylvania for the Promotion of the Mechanic Arts, in a letter from Philadelphia, informs us that a member of the institute, Mr. Samuel Insull, president of the Chicago Commonwealth Edison Company, has founded a medal for the institute, to be known as the Franklin medal. The medal is to be awarded from time to time to workers in physical science or technology, without regard to country, whose efforts, in the opinion of the board of management of the Franklin Institute, have done most to advance our knowledge of physical science or its application. Mr. Insull provided the sum of 1200*l.* for the execution of the scheme, and about 200*l.* has been applied for the purpose of paying for the design of the medal and the necessary dies and diploma plates. The medal is of gold, and has an intrinsic value of about 15*l.* Should the income derived from the fund be more than sufficient to provide such medals, the institute may award the surplus as premiums to accompany the medals. The medal has been designed by Dr. R. Tait McKenzie, of the University of Pennsylvania, and the accompanying illustration gives an idea of its general character.

Reverse. Obverse.
The Franklin Medal. Two-thirds natural size.

The *Museum Journal* (vol. v., No. 2) describes an interesting collection of objects of Buddhist and Indian art, formed at Darjeeling, during a long residence, by Mr. A. Scott, which has been recently acquired by the Philadelphia Museum. Mr. Scott established close relations with the Tibetan Lamas, and the symbolism of the objects collected by him have been interpreted by Lama Dousand Up, of Darjeeling. Many of them are of Indian origin and display considerable artistic skill. The most valuable specimen is an ivory tablet representing the chief episodes in the life of Buddha. This is believed to be Assamese work of the fifth or sixth centuries A.D., and represents an early type of Buddhist iconography. Even more remarkable is, so far as can at present be ascertained, the only crystal statuette of Buddha known to collectors, that at Kandy, in Ceylon, being of Chinese manufacture, and comparatively modern. The collection also includes fine images of Dolma or Tara, the tutelary Tibetan goddess, of the eleven-headed Avalokitesvara, and of the Diamond Sow goddess, with some lamps and other examples of modern Nipalese art. The collection, while far from rivalling those of the British and India Museums, is of some importance, and its acquisition illustrates the interest in Indian art now shown in America.

The chief items in the October number of *British Birds* are a report, by Mr. M. Vaughan, on last year's inquiry into the relative numbers of summer migrants to this country, and notes, by the editor, on the recapture of marked birds.

The effects of the war are being so severely felt by the Selborne Society that in the October number of the *Selborne Magazine* an appeal is issued by the council urging all members to endeavour to increase the membership roll and to promote the interest of the society by such other means as lie in their power.

We have to acknowledge the receipt of an article by Mr. R. R. Parker, from vol. xxv. of the Proc. Boston Nat. Hist. Soc., on the New England flies of the family Sarcophagidæ, and of a second, by Mr. T. Southwell, from vol. x. of the Journ. and Proc. Asiat. Soc. Bengal, on the tape-worms of India and Ceylon.

It appears from the autumn number of *Bird Notes and News* that the nesting-boxes supplied to its constituents by the Royal Society for the Protection of Birds have hitherto been made in Germany; the industry is now, perforce, to be transferred to this country. The bird-sanctuary at Brean Down is reported to have been very successful during the past breeding-season; and it is also mentioned that perches and rests for birds have been fitted by Trinity House workmen, under the auspices of the society, to the South Bishop Lighthouse, Pembrokeshire.

Part ii. of vol. x. of Annals of the South African Museum is almost exclusively interesting to specialists, the contents including two papers by Mr. K. H. Barnard on the crustacean fauna of South Africa, with descriptions of many new species, and one by Miss G. Ricardo on the South African gadflies of the family Tabanidæ, also with diagnoses of new forms. Of somewhat wider interest is an account, by Mr. A. Raffray, of a strange-looking beetle taken in a termite-nest at Kim-

berley, and regarded as representing a new genus and species—*Gasterotropis poweri*—although closely related to the Indian Aphanetrix.

As announced in the *Morning Post* of October 8, the Natural History Museum has received the carcase of a female Sowerby's beaked whaled (*Mesoplodon bidens*), recently stranded at Rosslare, Ireland. Described by Sowerby in 1804, on the evidence of an individual washed ashore in Elgin four years previously, this cetacean is rarely met with, either in British or foreign waters, the present example being, it is stated, only the twelfth recorded from the coasts of the British Islands. It has been carefully dissected by Mr. W. P. Pycraft, who, we understand, has made some interesting observations with regard to the arrangement and relative proportions of certain of the visceral organs.

In the fourth part of vol. iv. of the Annals of the Transvaal Museum, Dr. E. C. N. van Hoepen continues his articles on the fossil reptiles of the Karroo beds, dealing in this instance with the lower jaw of the dicynodont Lystrosaurus (Ptychognathus). After describing the various elements which go to form this compound bone, the author refers to a paper by Mr. D. M. S. Watson, in the *Ann. Mag. Nat. Hist.* for December, 1912, in which he noticed that some of the features there described as distinctive of the lower jaw of Dicynodon do not accord with his own interpretation of the structure of that of Lystrosaurus. A re-examination of the lower jaws of both genera served to confirm Dr. van Hoepen's original diagnosis.

According to a communication from Messrs. G. H. Carpenter and T. R. Hewitt, in the October number of the *Irish Naturalist*, the vexed question as to the mode in which the maggots of warble-flies first effect entrance into the bodies of cattle has been finally settled. Hatched in many instances on the feet of their hosts, the minute maggots normally bore through the skin to the subjacent tissues, whence they eventually make their way to the back, where they encyst themselves in the well-known "warbles." Whether the second-stage maggots frequently observed in the gullets of cattle are merely enjoying a halt on their long subcutaneous journey from the limbs to the back, or whether they enter the mouth from outside, requires further investigation.

Reproductions of five beautiful autochrome photographs of the marvellous scenery—both as regards form and colour—of the Grand Canyon, Colorado, constitute an attractive and striking feature of the second (July) number of the Brooklyn Museum Quarterly. The letterpress includes a picturesque narrative, by Mr. R. C. Murphy, of a collecting cruise from Fernando Noronha to South Georgia, undertaken in 1912 on behalf of the museum. Lying as it does only $3\frac{1}{2}°$ south of the equator, and being cooled by a constant trade-wind, Fernando Noronha might be made one of the most productive islands in the world, instead of remaining the desolate convict-station of Brazil. In the Antarctic the party was chiefly occupied in observing whales, sea-elephants, and penguins and other birds, as well as in collecting such of the latter as were required for the museum. "On the South Georgia banks," writes the author, "the abundance of whales is nothing short of astounding, but as during our visit I sometimes saw eleven steamers hunting almost within hail of each other, and as twice that number often came into the ports with from two to ten whales apiece, the various species can scarcely hold their own many seasons longer."

The annual report of the Marine Biological Association of the West of Scotland for 1913 indicates that a considerable amount of advanced research work was done at the Millport Station during the year. Summaries of the results are given in the report of the superintendent, Mr. R. Elmhirst, and in abstracts of papers read at meetings of the association held in Glasgow. The most striking portion of the report is a lecture by Prof. E. W. MacBride, on some problems of marine biology, which gives a useful summary of the lecturer's recent researches on hybridisation of echinoderms.

The report of the Cullercoats Marine Laboratory for the year ending June, 1914, is characterised rather by the number of subjects studied and the extent of the ground covered than by the importance of the new information furnished on any particular subject. Prof. Meek's papers on trawling experiments and on migrations of plaice and dab deal with small numbers and do not furnish anything strikingly new. The discussion on the probable origin of the migrations is interesting and suggestive, but from the nature of the case it is entirely speculative. Work on races of herrings, commenced in 1912, has been continued. The number of fish measured is larger than in previous years, and this research is probably the most important contribution to fishery science in the report. Other papers deal with crabs and lobsters, mussel and lobster culture, and the pollution of the river Tyne. There are also two faunistic papers on hydrozoa by J. H. Robson.

The meteorological chart of the North Atlantic Ocean for October, published by the Meteorological Office, states that steamers crossing that ocean are not likely to experience much, if any, delay from fog. With the exception of a few small areas of mist, neither fog nor mist is probable south of the parallel of 40° N. and west of longitude 20° W. It is not unlikely, however, that thick weather may be experienced on parts of the coast of Africa; this is principally due to red dust blown seaward from the Sahara and to mist from marked changes of temperature of air and sea. December to April are said to be the months of maximum frequency of red dust.

We have received from Mr. J. Baxendell, the energetic meteorologist to the Southport Corporation, the report of the results of observations for the year 1913 at the exceptionally well equipped station at that place. Returns are regularly supplied to the Meteorological Office, together with telegraphic notice of all gales. In the course of the year the hourly statistics of the duration of winds from different directions (partially published in 1912) have been materially extended. These, when discussed, as promised, will throw much light on the climate

of Southport. With reference to the latter, Mr. Baxendell remarks that, owing to the sea breezes, all the summer months are cool by day; generally speaking, there is more sunshine in the afternoon than in the morning. July is the best month of the year for outdoor life; May and June, and even September, are more settled than August. The report includes, as usual, a very handy table of comparative climatological statistics at health resorts and large towns, compiled from Meteorological Office data.

In the Bulletin of the Calcutta Mathematical Society, vol. ii., part 1 (Calcutta University Press, 1914), a paper is published by Mr. Jibon M. Bose, on the equations of motion of a plane kite, with special reference to its equilibrium, small oscillations, and conditions of stability. The paper thus constitutes a solution of Problem 16 of Bryan's "Stability in Aviation" (p. 180). In the case in which the kite is a plane lamina without keels, the author, as might be expected, obtains cubic equations for the longitudinal and lateral stability. This result is in accordance with the corresponding results for an aeroplane in which certain roots of the biquadratics vanish unless the aeroplane is provided with auxiliary surfaces.

The *Morning Post's* "own correspondent" in Rome announces that Prof. Argentieri, of Aquila (there is no university in Aquila, and we do not find Prof. Argentieri's name in "Minerva"), has invented a "pocket" system of radio-telegraphy, in which apparatus costing twelve shillings is capable of intercepting messages from the Eiffel Tower, a distance of 730 miles, that the German Government has offered him a large sum of money for the system, and that he has patriotically refused it, preferring to place his invention at the service of his own Government. It is true that the aerial for receiving messages of high power need not necessarily be of great length, that a great deal of wire can be coiled up in the pocket and erected on light portable posts to a considerable height, and it is also true that the remaining apparatus, for receiving only, may be of small bulk, but one can well be sceptical as to the authenticity of such a statement as the above. Perhaps the time will come when a man may slip a telephone receiver over his head, put up an aluminium-framed umbrella, stand with his feet in a puddle, and, using a battery, induction coil, and a sending key disposed in various pockets, and a detector in his hat, communicate freely with friends a few hundred miles away. But we have not reached this point yet, and, at present prices, the aluminium umbrella alone would probably cost twelve shillings. We are willing to give Mr. Argentieri the full credit his invention deserves so soon as he has found an opportunity to explain its details or to demonstrate its capabilities, but, in the meantime, we cannot take seriously the description given in our contemporary.

The following forthcoming books are additional to those announced in our issue of last week:—In *Anthropology and Archaeology*: The Literature of the Ancient Egyptians, Dr. E. A. Wallis Budge; A History of the Egyptian People, Dr. E. A. Wallis Budge (J. M. Dent and Sons, Ltd.); Ægean Archæology, H. R. Hall (The Medici Society, Ltd.); A Hausa Phrase Book, with Medical and Scientific Vocabularies, A. C. Parsons; Contributions to the Ethnology of the Salish Tribes, J. A. Teit; Coos Texts, L. J. Frachtenberg (Oxford University Press). In *Geography and Travel*: Life and Death in the Antarctic, Sir D. Mawson, two vols., illustrated (W. Heinemann); Indo-China and its Primitive People, Capt. H. Baudesson, illustrated; The Roman Colonies of North Africa, and their Ruined Cities, R. Sturzenbecker, illustrated (Hutchinson and Co.); Geography of Eastern Asia, D. Paton (Oxford University Press); On the Trail of the Opium Poppy, Sir A. Hosie, two vols., illustrated (G. Philip and Son, Ltd.); Travels in the Middle East, Lieut. T. C. Fowle, illustrated; The Voyages of Capt. Scott, retold by C. Turley, illustrated (Smith, Elder and Co.). In *Mathematics and Physical Science*: Electric Waves, Prof. G. W. Pierce; The Emission of Electricity from Hot Bodies, Prof. O. W. Richardson; Colloidal Solutions, Prof. E. F. Burton; Atmospheric Ionization, Prof. J. C. McLennan (each in the series of Monographs on Physics), (Longmans and Co.); Elementary Principles in Statistical Mechanics, Prof. J. Willard Gibbs (Oxford University Press). In *Medical Science*: The Evolution of Modern Medicine, Sir W. Osler (Oxford University Press). In *Metallurgy*: Zinc, Dr. J. S. G. Primrose; Aluminium, Dr. R. Seligmann; Metallurgy of Strain, S. C. W. Humfrey; Brass, G. D. Bengough; Refractory Metals, W. C. Hancock (Constable and Co., Ltd.). In *Technology*: Electrical Installation Manuals on Conductors, House Wiring, etc.; Lamps, Switches, Fittings, Transformers; Bells, Telephones, etc.; Testing and Localizing Faults (Constable and Co., Ltd.); Architectural Acoustics, W. C. Sabine (Oxford University Press).

A new and cheaper edition of the late Dr. Alfred Russel Wallace's book, "The World of Life: a Manifestation of Creative Power, Directive Mind, and Ultimate Purpose," has been published by Messrs. Chapman and Hall, Ltd. In its original form the work was reviewed at length in our issue for June 8, 1911 (vol. lxxxvi., p. 481), and it will be sufficient here to say that it can now be obtained at the price of 6*s*. net.

OUR ASTRONOMICAL COLUMN.

Comet 1913*f* (Delavan).—M. P. Puiseux communicates to the *Comptes rendus* for September 28 (vol. clix., No. 13) an account of photographs of Delavan's comet (1913*f*) which have been obtained at the Paris Observatory with the Henry-Gautier equatorial on September 5 and 6. The plates are impressed with a réseau, and each shows at least six stars which figure in the catalogues of the Astronomische Gesellschaft, executed at Bonn and Cambridge, together with a large number of fainter stars. Thus the necessary data are available for the determination of two accurate positions of this object. The comet on these dates was a little fainter than a 3·3 magnitude star. M. Coggia, in the same number of the *Comptes rendus*, gives five observations of positions of this comet made between September 14 and 18. On these dates the comet presented a round nucleus of about magnitude 5 with a tail of about 1° in length.

A Central Bureau for Transmission of Astronomical News.—At the present time astronomers have no available organisation by which the news of important astronomical discoveries can be quickly distributed to the leading observatories of the world, nor is there a bureau with which anyone making an important discovery can immediately communicate with the knowledge that the news will at once be circulated world wide. This condition of affairs is due to the fact that the recognised Central Bureau is at Kiel, in Germany, and that the state of war prevents the circulation of any such news. No steps, so far as is known, are being taken to remedy this defect, and for this reason the attention of astronomers should be directed to the necessity of some definite action to correct this unsatisfactory state of affairs. There is little doubt that if the Royal Astronomical Society of Great Britain would undertake, even if only as a temporary measure, the task of receiving and disseminating astronomical information, this act would meet with the approval of astronomers all the world over. Perhaps the council of this society might be persuaded to consider this suggestion at their next meeting. In the meantime a useful purpose might be served if astronomers at home and abroad stated their views on the subject so that proper steps can be taken for the formation of a permanent astronomical bureau.

The Sidereal Centre of the Universe.—That brilliant star, Canopus, or α Argus, more familiar to those who live in southern latitudes, has been brought into prominence by the interesting communication made to *Knowledge* in the August issue. In discussing the positions in space of the helium, or B stars, which stars, whether faint or bright, are situated at vast distances from us, and are free from preferential motion or star streaming, Mr. O. R. Walkey is led to conclude that peculiar interest becomes attached to the star Canopus in that it occupies the approximate position derived for the centre of the stellar system. In the article in question he gives his reasons for concluding that the distance of this star is of the same order as that indicated for this helium star centre, that Canopus appears to be stationary with reference to these helium stars, that its luminosity and mass are in character with their suggested significance, that the relative motions of the faint stars in the vicinity of Canopus indicate an orbital motion confirming the independently derived mass, and finally that the component of the solar motion tangential to Canopus indicates the existence of such a mass at the given distance. While the author makes it clearly understood that the views set forth do not prove the central position of Canopus, yet he shows that the evidence brought forward from many points of view all point consistently in the same direction.

THE ITALIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The report of the seventh meeting of the Italian Society for the Advancement of Science, which was held in Siena in September, 1913, has been recently issued; it contains a full account of the meeting and of the papers read before the society. The report contains pp. lviii + 1091, and is a striking testimony to the rapid development of the society, which is now only in its seventh year of existence, the first meeting having been held at Parma in 1907. The work of the society is divided broadly into three classes, Class A being devoted to the physical and mathematical sciences, with five sections—astronomy and mathematics; physics and applied mechanics, including electrotechnics; chemistry; mineralogy and geology; and geography. Class B includes the biological sciences, and is divided into four sections, dealing respectively with anatomy and zoology; botany and agriculture; physiology; pathology and hygiene. Class C comprises the moral sciences, and is subdivided into eight sections—archæology and the history of art; the history of science; philology; economic and social sciences; legal sciences; philosophy; history and the history of religion.

The meeting was opened by Prof. Pietro Rossi, the rector of the University of Siena, the inaugural address being delivered by Prof. Antonio Garbasso, who chose as his subject "The Principles of Mechanics." General addresses were delivered by Prof. G. Pighini on nervous energy and the chemico-physics of protoplasm; by Colonel E. Caviglia on the work executed in Libya by the Institute of Military Geography; and by Prof. A. Sclavo on the laws of hygiene. Prof. E. Manasse gave an address on the mineral resources of the Sienese territory, Prof. Valenti on the conditions and problems of the colony of Erythrea, Prof. F. Ferrara on the Mahometan law in the districts of Tripoli and Cyrene, and Prof. Rossi on the character of Sienese art from medieval times to the renaissance.

Among the sectional addresses the following may be mentioned:—Prof. S. Lussana on the thermodynamics of gases and liquids in reference to practical applications; Prof. A. Pochettino, fluorescence and phosphorescence; Prof. C. Acqua, the liberation of energy in the respiratory processes of plants; Prof. R. Pirotta, the alternation of generations in lower plants; Dr. M. Almagià, our present knowledge of malignant tumours; Prof. E. Centanni, new studies of the "formative stimulus"; Prof. E. Ficalbi, on F. C. Marmocchi, a pre-Darwinian evolutionist, and his views; Prof. C. Ulpiani, applications of thermodynamics to biology; Prof. D. Barduzzi, the Galilean method in the medical sciences; Prof. B. Varisco, science and the theory of science; Prof. R. Pettazzoni, the origin of the idea of God; Prof. C. Parvopassu; recent progress in the science and technics of construction; Prof. P. Gucci, the ideas of Galileo on the divisibility of matter; Prof. E. Carusi, the relation between Roman law and Mahometan law; Prof. C. De Stefani, recent American theories in geology.

Of the numerous papers read before the different sections and printed in full in the report it is possible here only to give the titles of a few which possess some general interest. In Class A, Prof. T. Levi Civita read a paper on the Torricellian theorem; Prof. G. Testa on a modification of Atwood's machine; Prof. M. Panetti on testing light motors at the aeronautical laboratory of the Turin Polytechnic; Captain G. Costanzi on aerodynamic and hydrodynamic tests in connection with aeroplanes; G. Ivaldi on the true kinetic theory of gases. Prof. M. Berti and Dr. S. Ciocchetti, a new type of phototropic substances; Profs. L. Francesconi and N. Granata, the constitution of the cyclic ketones of oil of santolin.

In Class B, Prof. R. Perotti, a general scheme for the utilisation of town sewage; Prof. R. Bargagli-Petrucci, the biological origin of the soil of Siena; Prof. G. Pollacci, on the bioreaction of tellurium and its application to the study of physiology and vegetable pathology; Prof. B. Bocci, the cerebral nerve-cell and its specific work; Prof. L. Sabbattani, colloidal carbon; Prof. A. Constantino, experiments on amino-acids; Prof. F. Nassetti, comparative study of plant and animal tumours; Prof. V. Sebastiani, influence of diet on tumours.

In Class C (moral sciences) only a few of the numerous papers read can be referred to. Prof. E. Fornasari di Verce dealt with the relation between

the birth- and death-rate of Italy; Prof. F. Filomusi-Guelfi, with modern idealism and the philosophy of law; Prof. A. Fracassini, the beginnings of the struggle of the Roman Empire against Christianity.

The meeting of the society lasted for five days, from Monday, September 22, to Friday, September 26, 1913.

RAINFALL OBSERVATIONS.

A USEFUL discussion by Prof. A. G. McAdie on the rainfall of California forms No. 4, vol. i., of the *University of California Publications in Geography*. The data used are chiefly the records of the U.S. Weather Bureau and extend for some localities over a period of sixty-three years. Among the chief factors controlling the rainfall of the State may be mentioned its diversified topography, the prevalent westerly winds from the Pacific Ocean, and the relatively cold California current. For convenience of discussion, the State has been divided into five sections, bearing some relation to the principal watersheds, and for each division are given the notable climatic features and a general statement of the distribution of rainfall and of its variation with altitude, while more detailed information is shown by tables and plates. Summer in California is practically rainless, but for other seasons certain portions of the State are considered by the author as lying within the zone of maximum intensity of rainfall in the United States. The greatest annual amount during the past ten years was 153½ in. in Del Norte County, and amounts exceeding 100 in. have occurred at many places. Apparently the heaviest monthly fall in the United States (71½ in.) occurred at Helen Mine (Cal.) in January, 1909. The rainfall of San Francisco is dealt with in considerable detail; the annual mean (sixty-four years) was 22·6 in., maximum yearly fall 38·8 in., minimum 9·3 in. The longest drought was 175 days in the summer half year of 1903.

As a supplement to "Rainfall Observations" for the year 1912, the Norwegian Meteorological Institute has published a volume (with charts) giving mean and extreme values of rainfall since its establishment towards the end of 1866. During the first few years of its existence the stations were few, but in 1912 the number reached 492. The tables include *inter alia* five-yearly means for 1876–1910, normal monthly and yearly values and extremes and days of rain and snow for the total number of years available, with summaries of days with amounts varying from 0·1 to 1·0 mm. The charts include normal yearly values (isohyets) for 1876–1910. These show very clearly the effect of storms and topography upon the rainfall. The curves along the south-west and west shores, which lie in the direct track of cyclonic depressions, show that the normal amounts range from 1000–1600 mm., while in districts not far inland amounts of 2000–3000 mm. are not unusual. In the more northerly and inland parts the values range from 600–1000 mm., and still less, especially in the extreme north-eastern districts. The work is a very valuable contribution to the climatology of an extensive tract, reaching beyond the 71st parallel of latitude.

The report of the director of the Egyptian Meteorological Service (Mr. J. I. Craig) on the rains of the Nile Basin and the Nile flood of 1912 follows the general lines of its predecessors. During the year rainfall was measured at 112 stations, and that recorded at 143 other places was taken into account. On the whole of the year rains were in excess on the eastern slopes of East Africa and of the Red Sea, but normal to weak everywhere else. The differences from the mean, and the average deviations by districts, are shown by tables, as usual. Mr. Craig states that the low stage of the river in 1912 was very poor, and that lower gauges were touched on the Bahr el Jebel than ever before. The flood was late; it was not until the beginning of August that the gauge at Wadi Halfa rose above normal, after which it continued so until August 21. A chapter is devoted to the extension of the usual equation for the flow of water in open channels, to include all the factors which affect the discharge, and the theory is applied to calculate the losses on the White Nile in the beginning of the year in question. The report concludes with the readings of the chief river gauges in Egypt and the Sudan.

THE AUSTRALIAN MEETING OF THE BRITISH ASSOCIATION.

SUB-SECTION A.

COSMICAL PHYSICS.

Opening Address by Prof. E. W. Brown, F.R.S., Chairman of the Sub-Section.

To one who has spent many years over the solution of a problem which is somewhat isolated from the more general questions of his subject, it is a satisfaction to have this opportunity for presenting the problem as a whole instead of in the piecemeal fashion which is necessary when there are many separate features to be worked out. In doing so, I shall try to avoid the more technical details of my subject as well as the temptation to enter into closely reasoned arguments, confining myself mainly to the results which have been obtained and to the conclusions which may be drawn from them.

In setting forth the present status of the problem, another side of it gives one a sense of pleasure. When a comparison between the work of the lunar theorist and that of the observer has to be made, it is necessary to take into consideration the facts and results obtained by astronomers for purposes not directly connected with the moon: the motions of the earth and planets, the position of the observer, the accuracy of star catalogues, the errors of the instruments used for the measurement of the places of celestial objects, the personality of the observers—all these have to be considered; in fact, almost every one of the departments of the astronomy of position must be drawn upon to furnish necessary data. The time has now arrived when it may perhaps be possible to repay in some measure the debt thus contracted by furnishing to the astronomer, and perhaps also the student of geodesy, and, if I may coin a word, of selenodesy, some results which can be deduced more accurately from a study of the moon's motion than in any other way. A long-continued exploration with few companions which ultimately leads to territories where other workers have already blazed paths gives the impression of having emerged from the thick jungle into open country. The explorer can once more join forces with his brother astronomers. He can judge his own results more justly and have them judged by others. If, then, an excuse be needed for overstepping the limits which seem, by silent consent, to have been imposed on those who devote themselves to lunar problems, it consists in a desire to show that these limits are not necessary and that a study of the motion of the moon can be of value and can contribute its share to the common funds of astronomy.

The history of the motion of the moon has been for more than two centuries a struggle between the theorists and the observers. Ever since the publication of the "Principia" and the enunciation of the law of gravitation by Isaac Newton, a constant effort

has been maintained to prove that the moon, like the other bodies of the solar system, obeyed this law to its farthest consequences. While the theory was being advanced, the observers were continually improving their instruments and their methods of observing, with the additional advantage that their efforts had a cumulative effect; the longer the time covered by their observations, the more exact was the knowledge obtained. The theorist lacked the latter advantage; if he started anew he could only use the better instruments for analysis provided by the mathematician. He was always trying to forge a plate of armour which the observer with a gun the power of which was increasing with the time could not penetrate. In the struggle the victory rarely failed to rest with the observer. Within the last decade we theorists have made another attempt to forge a new plate out of the old materials; whether we have substantially gained the victory must rest partly on the evidence I have to place before you to-day and partly on what the observer can produce in the near future.

There are three well-defined periods in the history of the subject so far as a complete development of the moon's motion is concerned. From the publication of the "Principia" in 1687, when Newton laid down the broad outlines, until the middle of the eighteenth century, but little progress was made. It seems to have required more than half a century for analysis by symbols to advance sufficiently far for extensive applications to the problems of celestial mechanics. Clairaut and d'Alembert both succeeded in rescuing the problem from the geometrical form into which Newton had cast it and in reducing it to analysis by the methods of the calculus. They were followed by Leonard Euler, who in my opinion is the greatest of all the successors of Isaac Newton as a lunar theorist. He initiated practically every method which has been used since his time, and his criticisms show that he had a good insight into their relative advantages. A long roll of names follows in this period. It was closed by the publication of the theories of Delaunay and Hansen and the tables of the latter, shortly after the middle of the nineteenth century. From then to the end of the century the published memoirs deal with special parts of the theory or with its more general aspects, but no complete development appeared which could supersede the results of Hansen.

My own theory, which was completed a few years ago, is rather the fulfilment to the utmost of the ideas of others than a new mode of finding the moon's motion. Its object was severely practical—to find in the most accurate way and by the shortest path the complete effect of the law of gravitation applied to the moon. It is a development of Hill's classic memoir of 1877. Hill in his turn was indebted to some extent to Euler. His indebtedness would have been greater had he been aware of a little-known paper of the latter, "Sur la Variation de la Lune," in which the orbit, now called the variation orbit, is obtained, and its advantages set forth in the words: "Quelque chimérique cette question j'ose assurer que, si l'on réussissoit à en trouver une solution parfaite on ne trouveroit presque plus de difficulté pour déterminer le vraî mouvement de la Lune réelle. Cette question est donc de la dernière importance et il sera toujours bon d'en approfondir toutes les difficultés, avant qu'on en puisse espérer une solution complète."

In the final results of my work the development aims to include the gravitational action of every particle of matter which can have a sensible effect on the moon's motion, so that any differences which appear between theory and observation may not be set down to want of accuracy in the completeness with which the theory is carried out. Every known force capable of calculation is included.

So much for the theory. Gravitation, however, is only a law of force; we need the initial position, speed, and direction of motion. To get this with sufficient accuracy no single set of observations will serve; the new theory must be compared with as great a number of these as possible. To do this directly from the theory is far too long a task, and, moreover, it is not necessary. In the past every observation has been compared with the place shown in the "Nautical Almanac," and the small differences between them have been recorded from day to day. By taking many of these differences and reducing them so as to correspond with differences at one date, the position of the moon at that date can be found with far greater accuracy than could be obtained through any one observation. At the Greenwich Observatory the moon has been observed and recorded regularly since 1750. With some 120 observations a year, there are about 20,000 available for comparison, quite apart from shorter series at other observatories. Unfortunately these observations are compared with incorrect theories, and, in the early days, the observers were not able to find out, with the accuracy required to-day, the errors of their instruments or the places of the stars with which the moon was compared. But we have means of correcting the observations, so that they can be freed from many of the errors present in the results which were published at the time the observations were made. We can also correct the older theories. They can be compared with the new theory and the differences calculated; these differences need not even be applied to the separate observations, but only to the observations combined into properly chosen groups. Thus the labour involved in making use of the earlier observations is much less than might appear at first sight.

For the past eighteen months I have been engaged in this work of finding the differences between the old theories and my own, as well as in correcting those observations which were made at times before the resources of the astronomer had reached their present stage of perfection. I have not dealt with the observations from the start; other workers, notably Airy, in the last century, and Cowell in this, have done the greater part of the labour. My share was mainly to carry theirs a stage further by adopting the latest theory and the best modern practice for the reduction of the observations. In this way a much closer agreement between theory and observation has been obtained, and the initial position and velocity of the moon at a given date are now known with an accuracy comparable with that of the theory. I shall shortly return to this problem and exhibit this degree of accuracy by means of some diagrams which will be thrown on the screen.

I have spoken of the determination of these initial values as if it constituted a problem separate from the theory. Theoretically it is so, but practically the two must go together. The increase in accuracy of the theory has gone on successively with increase in accuracy of the determination of these constants. We do not find, with a new theory, the new constants from the start, but corrections to the previously adopted values of these constants. In fact, all the problems of which I am talking are so much interrelated that it is only justifiable to separate them for the purposes of exposition.

Let us suppose that the theory and these constants have been found in numerical form, so that the position of the moon is shown by means of expressions which contain nothing unknown but the time. To

find the moon's place at any date we have then only to insert that date and to perform the necessary numerical calculations. This is not done directly, on account of the labour involved. What are known as "tables of the Moon's Motion" are formed. These tables constitute an intermediate step between the theory and the positions of the moon which are printed in the "Nautical Almanac." Their sole use and necessity is the abbreviation of the work of calculation required to predict the moon's place from the theoretical values which have been found. For this reason, the problem of producing efficient tables is not properly scientific; it is mainly economic. Nevertheless, I have found it as interesting and absorbing as any problem which involves masses of calculation is to those who are naturally fond of dealing with arithmetical work. My chief assistant, Mr. H. B. Hedrick, has employed his valuable experience in helping me to devise new ways of arranging the tables and making them simple for use.

A table is mainly a device by which calculations which are continually recurring are performed once for all time, so that those who need to make such calculations can read off the results from the table. In the case of the moon, the tables go in pairs. Each term in the moon's motion depends on an angle, and this angle depends on the date. One table gives the value of the angle at any date (a very little calculation enables the computer to find this), and the second table gives the value of the term for that angle. As the same angles are continually recurring, the second table will serve for all time.

We can, however, do better than construct one table for each term. The same angle can be made to serve for several terms, and consequently one table may be constructed so as include all of them. In other words, instead of looking out five numbers for five separate terms, the computer looks out one number which gives him the sum of the five terms. The more terms we can put into a single table the less work for the astronomer who wants the place of the moon, and therefore the more efficient the tables. A still better device is a single table which depends on two angles, known as a double-entry table; many more terms can usually be included in this than in a single-entry table. The double interpolation on each such table is avoided by having one angle the same for many double-entry tables and interpolating for that angle on the sum of the numbers extracted from the tables.

The problem of fitting the terms into the smallest number of tables is a problem in combinations—something like a mixture of a game at chess and a picture-puzzle, but unlike the latter in the fact that the intention is to produce ease and simplicity instead of difficulty. This work of arrangement is now completed, and, in fact, about five-sixths of the calculations necessary to form the tables are done; more than one-third of the copy is ready for the printer, but, owing to the large mass of the matter, it will take from two to three years to put it through the press. The cost of performing the calculations and printing the work has been met from a fund specially set aside for the purpose by Yale University.

A few statistics will perhaps give an idea of our work. Hansen has 300 terms in his three co-ordinates, and these are so grouped that about a hundred tables are used in finding a complete place of the moon. We have included more than 1000 terms in about 120 tables, so that there are on the average about eight terms per table. (In one of our tables we have been able to include no fewer than forty terms.) Each table is made as extensive as possible in order that the interpolations—the bane of all such calculations—shall be easy. The great majority of them involve multiplications by numbers less than 100. There are fewer than ten tables which will involve multiplications by numbers between 100 and 1000, and none greater than the latter number. The computer who is set to work to find the longitude, latitude, and parallax of the moon will not need a table of logarithms from the beginning to the end of his work. The reason for this is that all multiplications by three figures or less can be done by Crelle's well-known tables or by a computing machine. But Mr. Hedrick has devised a table for interpolation to three places which is more rapid and easy than either of these aids. It is, of course, of use generally for all such calculations, and arrangements are now being made for the preparation and publication of his tables. The actual work of finding the place of the moon from the new lunar tables will, I believe, not take more time—perhaps less—than from Hansen's tables, so soon as the computer has made himself familiar with them. Fortunately for him, it is not necessary to understand the details of their construction; he need only know the rules for using them.

I am now going to show by means of some diagrams the deviations of the moon from its theoretical orbit, in which, of course, errors of observation are included. The first two slides exhibit the average deviation of the moon from its computed place for the past century and a half in longitude.[1] The averages are taken over periods of 414 days and each point of the continuous line shows one such average. The dots are the results obtained by Newcomb from occultations; the averages for the first century are taken over periods of several years, and in the last sixty years over every year. In both cases the same theory and the same values of the constants have been used. Only one empirical term has been taken out—the long-period fluctuation found by Newcomb having a period of 270 years and a coefficient of 13″. I shall show the deviations with this term included, in a moment.

The first point to which attention should be directed is the agreement of the results deduced from the Greenwich meridian observations and those deduced from occultations gathered from observatories all over the world. There can be no doubt that the fluctuations are real and not due to errors of observation. A considerable difference appears about 1820, for which I have not been able to account, but I have reasons for thinking that the difference is mainly due to errors in the occultations rather than in the meridian values. In the last sixty years the differences become comparatively small, and the character of the deviation of the moon from its theoretical orbit is well marked. This deviation is obviously of a periodic character, but attempts to analyse it into one or two periodic terms have not met with success; the number of terms required for the purpose is too great to allow one to feel that they have have a real existence, and that they would combine to represent the motion in the future. The straight line character of the deviations is a rather marked peculiarity of the curves.

The actual deviations on a smaller scale are shown in the next slide; the great empirical term has here been restored and is shown by a broken line. The continuous line represents the Greenwich meridian observations; the dots are Newcomb's results for the occultations before 1750, the date at which the meridian observations begin. With a very slight amount of smoothing, especially since 1850, this diagram may be considered to show the actual deviations of the moon from its theoretical orbit.

The next slide shows the average values of the eccentricity and of the position of the perigee.[2] The

[1] *Monthly Notices, R.A.S.*, vol. lxxiii., plate 22.

[2] Tables II. and III. of a paper on "The Perigee and Eccentricity of the Moon," *Monthly Notices, R.A.S.*, March, 1914.

deviations are those from the values which I have obtained. It is obvious at once that there is little or nothing systematic about them; they may be put down almost entirely to errors of observation. The diminishing magnitude of the deviations as time goes on is good evidence for this; the accuracy of the observations has steadily increased. The coefficient of the term on which the eccentricity depends is found with a probable error of 0·02″, and the portion from 1750 to 1850 gives a value for it which agrees with that deduced from the portion 1850 to 1901 within 0·01″. The eccentricity is the constant which is now known with the highest degree of accuracy of any of those in the moon's motion. For the perigee there was a difference from the theoretical motion which would have caused the horizontal average in the curve to be tilted up one end more than 2″ above that at the other end. I have taken this out, ascribing it to a wrong value for the earth's ellipticity; the point will be again referred to later. The actual value obtained from the observations themselves has been used in the diagram, so that the deviations shown are deviations from the observed value.

The next slide shows the deviations of the mean inclination and the motion of the node, as well as of the mean latitude from the values deduced from the observations.[3] In these cases the observations only run from 1847 to 1901. It did not seem worth while to extend them back to 1750, for it is evident that the errors are mainly accidental, and the mean results agreed so closely with those obtained by Newcomb from occultations that little would have been gained by the use of the much less accurate observations made before 1847. The theoretical motion of the node differs from its observed value by a quantity which would have tilted up one end of the zero line about 0·5″ above the other; the hypothesis adopted in the case of perigee will account for the difference.

The mean latitude curve is interesting. It should represent the mean deviations of the moon's centre from the ecliptic; but it actually represents the deviations from a plane 0·5″ below the ecliptic. A similar deviation was found by Newcomb. Certain periodic terms have also been taken out. The explanation of these terms will be referred to directly.

The net result of this work is a determination of the constants of eccentricity, inclination, and of the positions of the perigee and node with practical certainty. The motions of the perigee and node here agree with their theoretical values when the new value of the earth's ellipticity is used. The only outstanding parts requiring explanation are the deviations in the mean longitude. If inquiry is made as to the degree of accuracy which the usual statement of the gravitation law involves, it may be said that the index which the inverse square law contains does not differ from 2 by a fraction greater than 1/400,000,000. This is deduced from the agreement between the observed and theoretical motions of the perigee when we attribute the mean of the differences found for this motion and for that of the node to a defective value of the ellipticity of the earth.

I have mentioned the mean deviation of the latitude of the moon from the ecliptic. There are also periodic terms with the mean longitude as argument occurring both in the latitude and the longitude. My explanation of these was anticipated by Prof. Bakhuysen by a few weeks. The term in longitude had been found from two series of Greenwich observations, one of twenty-eight and the other of twenty-one years, by van Steenwijk, and Prof. Bakhuysen, putting this with the deviations of the mean latitude found by Hansen and himself, attributed them to systematic irregularities of the moon's limbs.

What I have done is to find (1) the deviation of the mean latitude for sixty-four years; (2) a periodic term in latitude from observations covering fifty-five years; and (3) a periodic term in longitude from observations covering 150 years, the period being that of the mean longitude. Further, if to these be added Newcomb's deviations of the mean latitude derived (*a*) from immersions and (*b*) from emersions, we have a series of five separate determinations—separate because the occultations are derived from parts of the limb not wholly the same as those used in meridian observations. Now all these give a consistent shape to the moon's limb referred to its centre of mass. This shape agrees qualitatively with that which may be deduced from Franz's figure.

I throw on the screen two diagrammatic representations[4] of these irregularities obtained by Dr. F. Hayn from a long series of actual measures of the heights and depths of the lunar formations. The next slide shows the systematic character more clearly. It is from a paper by Franz.[5] It does not show the character of the heights and depths at the limb, but we may judge of these from the general character of the high and low areas of the portions which have been measured and which extend near to the limbs. I think there can be little doubt that this explanation of these small terms is correct, and if so it supplies a satisfactory cause for a number of puzzling inequalities.

The most interesting feature of this result is the general shape of the moon's limb relative to the centre of mass and its relation to the principle of isostasy. Here we see with some definiteness that the edge of the southern limb in general is further from the moon's centre of mass than the northern. Hence we must conclude that the density at least of the crust of the former is less than that of the latter, in accordance with the principle mentioned. The analogy to the figure of the earth with its marked land and sea hemispheres is perhaps worth pointing out, but the higher ground in the moon is mainly on the south of its equator, while that on the earth is north. Unfortunately we know nothing about the other face of the moon. Nevertheless it seems worth while to direct the attention of geologists to facts which may ultimately have some cosmogonic applications. The astronomical difficulties are immediate: different corrections for meridian observations in latitude, in longitude, on Mösting A, for occultations and for the photographic method, will be required.

I next turn to a question, the chief interest of which is geodetic rather than astronomical. I have mentioned that a certain value of the earth's ellipticity will make the observed motions of the perigee and node agree with their theoretical values. This value is 1/293·7±0·3. Now Helmert's value obtained from gravity determinations is 1/298·3. The conference of "Nautical Almanac" directors in 1911 adopted 1/297. There is thus a considerable discrepancy. Other evidence, however, can be brought forward. Not long ago a series of simultaneous observations at the Cape and Greenwich Observatories was made in order to obtain a new value of the moon's parallax. After five years' work a hundred simultaneous pairs were obtained, the discussion of which gives evidence of their excellence. Mr. Crommelin, of the Greenwich Observatory, who undertook this discussion, determined the ellipticity of the earth by a comparison between the theoretical and observed values of the parallax.

[3] "The Mean Latitudes of the Sun and Moon." *Monthly Notices, R.A.S.*, January, 1914: "The Determination of the Constants of the Node, the Inclination, the Earth's Ellipticity, and the Obliquity of the Ecliptic." *ibid.*, June, 1914.

[4] *Abh. der Math.-Phys. Kl. der Kön. Sächs. Ges. der Wiss.*, vols., xxix., xxx.

[5] *Königsberger Astr. Beob.*, Abth., 38

He found an ellipticity 1/294·4±1·5 closely agreeing with that which I have obtained. Finally, Col. Clarke's value obtained from geodetic measures was 1/293·5. We have thus three quite different determinations ranging round 1/294 to set against a fourth determination of 1/298. The term in the latitude of the moon which has often been used for this purpose is of little value on account of the coefficient being also dependent on the value of the obliquity of the ecliptic; such evidence as it presents is rather in favour of the larger value. I omit Hill's value, obtained from gravity determinations, because it is obviously too large.

Here, then, is a definite issue. To satisfy the observations of the moon in at least three different parts, a value near 1/294 must be used; while the value most carefully found from gravity determinations is 1/298. So far as astronomy is concerned, the moon is the only body for which a correct value of this constant is important, and it would seem inadvisable to use a value which will cause a disagreement between theory and observation in at least three different ways. It is a question whether the conference value should not be changed with the advent of the new lunar tables.

In looking forward to future determinations of this constant, it seems to be quite possible that direct observations of the moon's parallax are likely to furnish at least as accurate a value of the earth's shape as any other method. This can be done, I believe, much better by the Harvard photographic method than by meridian observations. Two identical instruments are advisable for the best results, one placed in the northern and the other in the southern hemisphere from 60° to 90° apart in latitude, and as nearly as possible on the same meridian. On nights which are fine at both stations, from fifteen to twenty pairs of plates could be obtained. In a few months it is probable that some 400 pairs might be obtained. These should furnish a value for the parallax with a probable error of about 0·02″, and a value for the ellipticity within half a unit of the denominator 294. It would be still more interesting if the two instruments could be set up on meridians in different parts of the earth. The Cape and a northern observatory, Upsala, for example, would furnish one arc; Harvard and Ariquipa or Santiago another. If it were possible to connect by triangulation Australia with the Asiatic continent, a third could be obtained near the meridian of Brisbane. Or, accepting the observed parallax and the earth's ellipticity, we could find by observation the lengths of long arcs on the earth's surface with high accuracy.

In any case, I believe that the time must shortly come when the photographic method of finding the moon's place should be taken up more extensively, whether it be used for the determination of the moon's parallax and the earth's ellipticity or not. The Greenwich meridian observations have been, and continue to be, a wonderful storehouse for long series of observations of the positions of the sun, moon, planets, and stars. In the United States, Harvard Observatory has adopted the plan of securing continuous photographic records of the sky, with particular reference to photometric work. Under Prof. Pickering it will also continue the photographic record of the moon's position so long as arrangements can be made to measure the plates and compute the moon's position from them.

In spite of the fact that Harvard Observatory has undertaken to continue for the present the work of photographing the moon's position, I believe that this method should find a permanent home in a national observatory. It has already shown itself capable of producing the accuracy which the best modern observations of Greenwich can furnish, and no higher praise need be given. If this home could be found in the southern hemisphere, and more particularly in Australia, other advantages would accrue.

But we should look for more than this. In an observatory the first duty of which might be the securing of the best daily records of the sky, the positions of the sun, stars, planets, a couple of plates of the moon on every night when she is visible would be a small matter. What is needed is an organisation so constructed as to be out of the reach of changing governmental policy, with a permanent appropriation, and a staff of the highest character removed from all political influences. It could render immense service to astronomers, not only in the Empire, but all over the world. The pride which every Englishman feels who has to work with the records of the past furnished by Greenwich would in course of time arise from the work of a similar establishment elsewhere. Those of us who live in a community which, reckoning by the age of nations, is new, know that, in order to achieve objects which are not material, sacrifices must be made; but we also know that such sacrifices are beneficial, not only in themselves, but as exerting an indirect influence in promoting the cause of higher education and of scientific progress in every direction. In saying this, I am not advocating the cause of the few, but of the majority; the least practical investigations of yesterday are continually becoming of the greatest practical value to-day.

No address before this section is complete without some speculation and a glance towards the future. I shall indulge in both to some small extent before closing. I have shown you what the outstanding residuals in the moon's motion are: they consist mainly of long-period fluctuations in the mean longitude. I have not mentioned the secular changes because the evidence for them does not rest on modern observations, but on ancient eclipses, and these are matters too debatable to discuss in the limited time allotted to me for this address. It may be said, however, that the only secular motion which is capable of being determined from the modern observations, and is not affected by the discussion of ancient eclipses—namely, the secular motion of the perigee—agrees with its theoretical value well within the probable error. With this remark I pass to the empirical terms.

These unexplained differences between theory and observation may be separated into two parts. First, Newcomb's term of period between 250 and 300 years and coefficient 13″, and, secondly, the fluctuations which appear to have an approximate period of sixty to seventy years. The former appears to be more important than the latter, but from the investigator's point of view it is less so. The force depends on the degree of inclination of the curve to the zero line, or on the curvature, according to the hypothesis made. In either case the shorter period term is much more striking, and, as I have pointed out on several occasions, it is much more likely to lead to the sources of these terms than the longer period. It is also, at least for the last sixty years, much better determined from observation, and is not likely to be confounded with unknown secular changes.

Various hypotheses have been advanced within the last few years to account for these terms. Some of them postulate matter not directly observed, or matter with unknown constants; others, deviations of the Newtonian law from its exact expression; still others, non-gravitational forces. M. St. Blancat[6] examines

[6] *Annales de la Faculté des Sciences de Toulouse*, 1907.

a variety of cases of intramercurial planets, and arrives at the conclusion that such matter, if it exists, must have a mass comparable with that of Mercury. Some time ago I examined the same hypothesis, and arrived at similar results. The smallest planet with density four times that of water, which would produce the long inequality, must have a disc of nearly 2″ in its transit across the sun, and a still larger planet would be necessary to produce the shorter period terms. But observational attempts, particularly those made by Perrine and Campbell, have always failed to detect any such planet, and Prof. Campbell is of the opinion that a body with so large a disc could scarcely have been overlooked. If we fall back on a swarm instead of a single body, we replace one difficulty by two. The light from such a swarm would be greater than that from a single body, and would therefore make detection more likely. If the swarm were more diffused we encounter the difficulty that it would not be held together by its own attraction, and would therefore soon scatter into a ring; such a ring cannot give periodic changes of the kind required.

The shading of gravitation by interposing matter, *e.g.* at the time of eclipses, has been examined by Bottlinger.[7] For one reason alone, I believe this is very doubtful. It is difficult to see how new periodicities can be produced; the periods should be combinations of those already present in the moon's motion. The sixty to seventy years' fluctuation stands out in this respect because its period is not anywhere near any period present in the moon's motion or any probable combination of the moon's periods. Indeed, Dr. Bottlinger's curve shows this: there is no trace of the fluctuation.

Some four years ago I examined[8] a number of hypotheses. The motions of the magnetic field of the earth and of postulated fields on the moon had to be rejected, mainly because they caused impossible increases in the mean motion of the perigee. An equatorial ellipticity of the sun's mass, combined with a rotation period very nearly one month in length, appeared to be the best of these hypotheses. The obvious objections to it are, first, that such an ellipticity, small as it can be (about 1/20,000), is difficult to understand on physical grounds, and, secondly, that the rotation period of the nucleus which might be supposed to possess this elliptic shape in the sun's equator is a quantity which is so doubtful that it furnishes no help from observation, although the observed periods are well within the required limits. Dr. Hale's discovery of the magnetic field of the sun is of interest in this connection. Such a field, of non-uniform strength, and rotating with the sun, is mathematically exactly equivalent to an equatorial ellipticity of the sun's mass, so that the hypothesis might stand from the mathematical point of view, the expression of the symbols in words being alone different.

The last published hypothesis is that of Prof. Turner,[9] who assumes that the Leonids have finite mass, and that a big swarm of them periodically disturbs the moon as the orbits of the earth and the swarm intersect. I had examined this myself last summer, but rejected it because, although it explained the straight line appearance of the curve of fluctuations, one of the most important of the changes of direction in this curve was not accounted for. We have the further difficulty that continual encounters with the earth will spread the swarm along its orbit, so that with this idea the swarm should be a late arrival, and its periodic effect on the moon's motion of diminishing amplitude; with respect to the latter, the observed amplitude seems rather to have increased.

The main objection to all these ideas consists in the fact that they stand alone: there is as yet little or no collateral evidence from other sources. The difficulty, in fact, is not that of finding a hypothesis to fit the facts, but of selecting one out of many. The last hypothesis which I shall mention is one which is less definite than the others, but which does appear to have some other evidence in its favour.

The magnetic forces, mentioned above, were changes in the *directions* of assumed magnetic fields. If we assume changes in the intensities of the fields themselves, we avoid the difficulties of altering portions of the moon's motion other than that of the mean motion. We know that the earth's magnetic field varies and that the sun has such a field, and there is no inherent improbability in attributing similar fields to the moon and the planets. If we assume that variations in the strength of these fields arise in the sun and are communicated to the other bodies of the solar system, we should expect fluctuations having the same period and of the same or opposite phase but differing in magnitude. It therefore becomes of interest to search for fluctuations in the motions of the planets similar to that found in the moon's orbit. The material in available form for this purpose is rather scanty; it needs to be a long series of observations reduced on a uniform plan. The best I know is in Newcomb's "Astronomical Constants." He gives there the material for the earth arranged in groups of a few years at a time. The results for Mercury, given for another purpose, can also be extracted from the same place. For Venus and Mars, Newcomb unfortunately only printed the normal equations from which he deduces the constants of the orbit.

On the screen is shown a slide (see p. 190) which exhibits the results for the Earth and Mercury compared with those for the moon. In the uppermost curve are reproduced the minor fluctuations of the moon shown earlier; the second curve contains those of the earth's longitude; the third, those of Mercury's longitude. (By accident the mean motion correction has been left in the Earth curve; the zero line is therefore inclined instead of being horizontal.) It will be noticed that the scales are different and that the Earth curve is reversed. In spite of the fact that the probable errors of the results in the second and third curves are not much less than their divergences from a straight line, I think that the correlation exhibited is of some significance. If it is, we have here a force the period of which, if period in the strict sense it has, is the same as that of the effect: the latter is not then a resonance from combination with another period. We must therefore look for some kind of a surge spreading through the solar system and affecting planets and satellites the same way but to different degrees.

The lowest curve is an old friend, that of Wolf's sunspot frequency, put there, not for that reason, but because the known connection for the last sixty years between sunspot frequency and prevalence of magnetic disturbance enables us with fair probability to extend the latter back to 1750. With some change of phase the periods of high and low maxima correspond nearly with the fluctuations above. The eleven-year oscillation is naturally eliminated from the group results for the Earth and Mercury. One might expect it to be present in the lunar curve, but owing to its shorter period we should probably not obtain a coefficient of more than half a second. Notwithstanding this fact, it

[7] *Diss.*, Freiburg i., Br., 1912.
[8] *Amer. Jour. Sc.*, vol. xxix.
[9] *Monthly Notices*, December, 1913.

is a valid objection to the hypothesis that there is no evidence of it in the moon's motion. Reasons may exist for this: but until the mechanism of the action can be made more definite it is scarcely worth while to belabour the point.

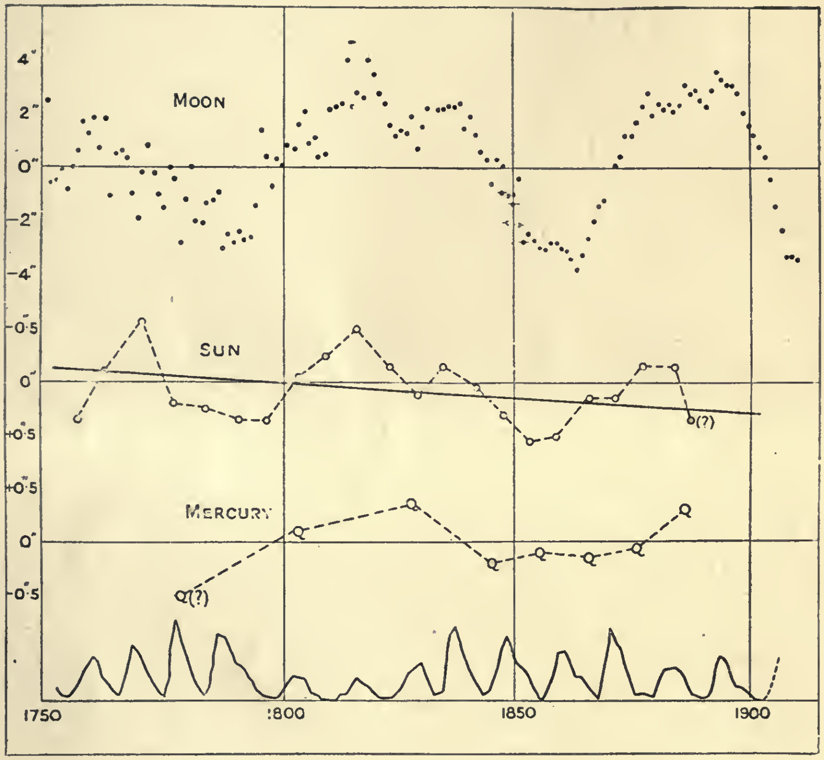
The hypothesis presents many difficulties. Even if one is disposed to admit provisionally a correlation between the four curves—and this is open to considerable doubt—it is difficult to understand how, under the electron theory of magnetic storms, the motions of moon and planets can be sensibly affected. I am perhaps catching at straws in attempting to relate two such different phenomena with one another, but when we are in the presence of anomalies which show points of resemblance and lack the property of analysis into strict periodic sequences some latitude may be permissible.

In conclusion, what, it may well be asked, is the future of the lunar theory now that the gravitational effects appear to have been considered in such detail that further numerical work in the theory is not likely to advance our knowledge very materially? What good purpose is to be served by continuous observation of the moon and comparison with the theory? I believe that the answer lies mainly in the investigation of the fluctuations already mentioned. I have not referred to other periodic terms which have been found because the observational evidence for their real existence rests on foundations much less secure. These need to be examined more carefully, and this examination must, I think, depend mainly on future observations rather than on the records of the past. Only by the greatest care in making the observations and in eliminating systematic and other errors from them can these matters be fully elucidated. If this can be achieved and if the new theory and tables serve, as they should, to eliminate all the known effects of gravitation, we shall be in a position to investigate with some confidence the other forces which seem to be at work in the solar system and at which we can now only guess. Assistance should be afforded by observations of the sun and planets, but the moon is nearest to us and is, chiefly on that account, the best instrument for their detection. Doubtless other investigations will arise in the future. But the solution of the known problems is still to be sought, and the laying of the coping stone on the edifice reared through the last two centuries cannot be a simple matter. Even our abler successors will scarcely exclaim, with Hotspur,

> "By heaven, methinks, it were an easy leap
> To pluck bright honour from the pale-faced moon."

They, like us and our predecessors, must go through long and careful investigations to find out the new truths before they have solved our difficulties, and in their turn they will discover new problems to solve for those who follow them:—

> "For the fortune of us, that are the moon's men, doth ebb and flow like the sea, being governed, as the sea is, by the moon."



UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. H. L. SMITH, formerly lecturer in chemistry at King's College, London, and in applied chemistry at King's College for Women, has succeeded Prof. A. W. Crossley in the chair of chemistry at the School of Pharmacy of the Pharmaceutical Society.

A COURSE of eight advanced lectures on the structure of crystals, will be given at the Battersea Polytechnic, London, S.W., by Dr. T. Martin Lowry, on Fridays, commencing October 23, at 7 p.m. The nominal fee for the whole course is one shilling.

A COURSE of eight public lectures will be given in the botanical department of University College (University of London), on the rôle of plants in the protection and growth of the shore, by Prof. F. W. Oliver, on Fridays, at 5 p.m., beginning to-morrow, October 16. The course is addressed to maritime engineers, botanists, and others interested in the phenomena of the shore.

MR. ERNEST J. EDWARDS has been appointed head of the Department of Geology in the Royal Technical College, Glasgow. This position was recently created by the subdivision of the Department of Mining and Geology. Mr. Edwards is a graduate of Leeds and of Manchester, and for some years past has been assistant lecturer and demonstrator in geology at University College, Cardiff.

A REUTER message from Cape Town on October 8 states that the report of the Government Commission dealing with the University question has been issued. The report recommends the establishment of two

universities, at Cape Town and Pretoria, composed of constituent colleges. The central seat of the reconstituted Cape University will be Groote Schuur, where it is proposed to erect two university buildings, designated the Wernher Hostel and Beit Hostel, for which 350,000*l.* of the Wernher-Beit gift of half a million will be utilised. The remainder of the gift it is proposed to devote to the other centres. The Commission suggests that the Pretoria college shall embrace the Transvaal, the Free State, and Natal.

THE calendar for the year 1914 of the National University of Ireland is now available. In it are printed the Irish Universities Act, 1908, the charter of the University and the various statutes. It will be remembered that the constituent colleges of the University are University College, Dublin; University College, Cork; and University College, Galway. In addition, St. Patrick's College, Maynooth, is a recognised college of the University. There are eight faculties in the University, namely, arts, philosophy and sociology, Celtic studies, science, law, medicine, engineering and architecture, and commerce. Full particulars are given as to the conditions under which degrees in these faculties are conferred, and also detailed information of the regulations and courses of the constituent colleges.

INTERESTING details as to the provision of facilities for higher instruction in agriculture for the counties in the north of Scotland are given in the 1914–15 calendar of the North of Scotland College of Agriculture. The classes of the college are held in the University of Aberdeen, except those in agricultural and field engineering, which are held in Robert Gordon's Technical College. Classes are arranged for the benefit of every section of the agricultural community, and there are courses of varying lengths at different seasons of the year, so that all grades of agricultural workers may utilise their leisure periods to the best advantage. The governors have acquired a college farm where experiments and demonstrations are carried out. Experimental plots, an experimental and demonstration garden, and a horticultural department are in course of construction. It is also intended to carry on feeding and other experiments upon stock. The farm is conveniently situated about five miles from Aberdeen. Students are expected to familiarise themselves with the experimental and other work upon the farm, on which demonstrations are carried out. There is a large area of timber, including both coniferous and hard wood trees. This is to be made use of for the purposes of the forestry department.

THE Department of Agriculture and Technical Instruction for Ireland has issued, for the present session, its programme of experimental science, drawing, manual instruction, and domestic economy for day secondary schools in Ireland, and it contains an explanatory circular and regulations. It is interesting to note in the circular to managers and principals of schools that they are informed that the efficiency of instruction will be tested by inspection, as a rule, without notice. It is, however, proposed that special inspections of a more thorough character shall be held, of which due notice will be given to the school managers. It is intended that such inspections shall not, as a rule, be held more frequently than once in three years for any one school. During the latter part of the school session notice will be given of a visit mainly for the purpose of holding the qualifying practical tests for candidates for honours. At any visit it will be within the discretion of the inspector to test any or all of the classes by practical exercises in the laboratory; by the examination of notebooks, etc.; by *viva voce* examination of classes or of individuals; by written examinations, or by a combination of these methods. The courses of instruction in these schools includes a preliminary obligatory two years' course, which may vary according to the character of the school, but must include experimental science and drawing. In subsequent years as many as three of a large number of special courses in pure and applied science may be taken, and, in the circumstances detailed, grants may be earned on the instruction.

A COPY has reached us of the forty-first annual report of the Canterbury College, of the University of New Zealand, together with a statement by the chairman of the governors and the accounts for the year 1913. Attached to the balance-sheet is a return showing the value of the various buildings and sites to be 129,794*l.* The total receipts from current revenue for the year amounted to 40,694*l.*, while the expenditure totalled 36,204*l.*, the surplus of income amounting to 4490*l.*, of which sum 3098*l.* was utilised in reducing overdraft. Grants and subsidies from the Government totalled 11,372*l.*, of which 3365*l.* was contributed towards the cost of new buildings. The total amount expended on salaries was 23,199*l.* Last year negotiations were being entered into with the governors of the Royal Holloway College with the view of a scholarship being established there in connection with Canterbury College to enable women students from the latter to continue their university studies at the London University as a post-graduate course. Such arrangements are now completed, the governors of the Holloway College have set aside a scholarship of 50*l.* per annum for the purpose. This has been subsidised by the governors of Canterbury College with 100*l.* per annum for two years, renewable for a third year if the home authorities recommend the extension of their scholarship. The chairman directed attention to the fact that the museum in connection with the college suffers financially from the fact that it is impossible to allocate a sufficiently large sum from its special source of revenue to meet even necessary requirements, and when extra expenditure becomes an absolute necessity, the amount set aside for maintenance will have to be curtailed. If no change takes place, it will become increasingly difficult to keep it in the position of being one of the leading museums south of the line, while the question of an additional wing seems for the present to be entirely beyond available resources.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 28.—M. P. Appell in the chair.—Remarks by M. Edmond **Perrier** on the life work of the late M. Jean Pérez.—P. **Puiseux**: The photographs of the Delavan comet 1913*f*, obtained at the Paris Observatory with the Henry-Gautier equatorial. From these photographs, taken September 5–6, the necessary elements can be obtained for determining very exactly two positions of the comet.—J. **Boussinesq**: The approximate evaluation of the constant of filtration μ, for a filtering medium composed of spherical grains of a given diameter.—M. **Coggia**: Observations of the Delavan comet made at the Observatory of Marseilles with the comet-finder. Positions are given for September 14–15 (two observations), 17–18, with positions of the comparison stars. The comet is visible to the naked eye with a tail of about 1°.—MM. **Luizet** and **Guillaume**: Observation of the solar eclipse of August 21, 1914, made at the Observatory of Lyons.—D. **Pompeiu**: A problem relating to abstract ensembles.—Ch. **Tanret**: The plurality of the amyloses. Determinations of the absolute and relative percentage of amyloses dissolved by water at different temperatures in sixteen different kinds of starches.

EXPERIMENTAL AND PHILOSOPHICAL BIOLOGY.

(1) *Experimental Zoologie.* By Dr. Hans Przibram. 4. Vitalität. (Lebenszustand.) Pp. viii+179+x plates. (Leipzig and Wien: Franz Deuticke, 1913.) Price 10 m.

(2) *Mechanism, Life and Personality.* An Examination of the Mechanistic Theory of Life and Mind. By Dr. J. S. Haldane. Pp. vii+139. (London: John Murray, 1913.) Price 2s. 6d. net.

(1) FROM the point of view of an experimental zoologist, Dr. Przibram has made a very valuable study of the distinctive characters of organisms, which may be ranked in three groups—structural, chemical, and functional. Organisms have a heterogeneous structure, showing at least cytoplasm and nucleoplasm, and they develop by self-differentiation. Organisms also show chemical differentiation, being built up of heterogeneous proteids in a colloidal state. Organisms grow in an active way: they utilise food different from themselves; they multiply in a manner certainly different from the division of crystals; they often show apparently spontaneous movements; and they have an unusual power of preserving impressions of previous states. It is interesting to notice how little agreement there is as yet among biologists as to the best way of stating these general characters of organisms. Przibram's is marked by a desire to avoid any exaggeration of the apartness of living creatures or any discouraging of the methods of mechanistic interpretation.

It is experimentally possible to mimic, with inorganic materials, the growth, movements, and even division of simple organisms, and a bowl of gelatine may illustrate the power of retaining traces of previous influences after the original conditions have been restored. Many beautiful experiments point to the conclusion that the geometrical forms displayed by many organisms, *e.g.* in their shells and skeletal parts, are expressions of the properties of the "aggregation-state" of the protoplasm. The polarity, likewise, of an organism admits of interpretation in terms of the "layering" or zonal distribution of different kinds of substances, and in similar ways.

The rapid advances of synthetic chemistry (only possible, however, through the directing intelligence of the chemist), show that we must not make too much of the chemical complexity of the proteids so characteristic of organisms; the difficulty as to the optically active nature of vital organic substances may be overcome; and the fact that fermentation- and oxidation-processes are slower when the living vehicles, *e.g.* yeast and red blood corpuscles, are absent, may be due to the greater concentration afforded by the organisation of the living cells. Living implies action and reaction between the organism and its environment; the continuance of the creature's activity depends on its structural organisation and on its specific series of chemical processes; violent death ensues when changes in the complex environment (chemical reagents, humidity, concentration, pressures, gravity, electricity, radiant energies, and temperature) fatally disturb the chemical processes, or break down the structure, or prevent the persistence of the organisation by disarranging the chemical routine.

Przibram has made many observations on the rate of growth in different types, and his general result takes us back to Herbert Spencer. A doubling of the mass of the living cell leads to the break-down of that cell, and the process is comparable to the "autokatalysis" observed in some non-vital chemical transformations. Surely in its movements, at least, the animal is spontaneous and unique. But the author bids us consider all the taxisms and tropisms—the inevitable responses which the creature makes in response to external stimuli—of light, heat, pressure, humidity and so on. He seems to us to lay on the shoulders of taxisms and tropisms a burden heavier than they can bear, and we do not think that what Jennings observed of an amœba on the hunt can be fully redescribed along these lines. It is plain, however, that the interpretation in terms of taxisms and tropisms must continue to be worked for all it is worth until we get quite below the stage of opinions. In answer to the common criticism that we see different answers given by the same or similar organisms to precisely similar stimuli, Przibram admits that we must take account of the physiological condition of the organism as affected by previous experiences, both personal and racial. This is a crucial point—whether inorganic bodies can be said to have "duration" in Bergson's sense—the power of continuing the past into the present. Przibram admits that living creatures have the power of registering the past in a notably high degree, but he declines to credit them with the exclusive possession of this quality, recalling for instance the facility with which a piece of steel is magnetised after it has been magnetised before.

As regards transformations of energy, organisms are marvellous engines, but they conform to the laws of thermodynamics. The conclusion arrived at is that we cannot assert that there operates in organisms any form of energy which is not

known in the inorganic domain. Of course, we have our psychical life, but can we say that this makes a thoroughgoing distinction between organisms and inanimate bodies? How can we tell? Thus there ends a masterly book—scholarly, keenly critical, and rigidly objective. We do not think that the author shows the sufficiency of chemico-physical formulæ for the description of the phenomena of life, but we have the strongest admiration for his searching criticism of the doctrine of the autonomy of the organism. His book should be read along with Johnstone's "Philosophy of Biology."

(2) "The time is now more than ripe," Dr. Haldane writes, "for bringing the great biological movement of the nineteenth century into definite relation with the main stream of human thought," and his lectures form an important contribution towards the fulfilment of this task. The first lecture contrasts the mechanistic and the vitalistic interpretations. The former is certainly good so far as it goes, for the living creature can be usefully considered as a very complex material system, conforming to the laws of dynamics, exhibiting physical and chemical processes that are in line with those of the inorganic world, and as for consciousness (if that be demonstrable) it makes no difference to the energy balance whether the organism is conscious or not. It is true that the activities of the organism are very wonderfully co-ordinated towards securing the survival of the individual and the race, but it is replied that there are effective nervous and chemical means which secure this co-ordination, and have been wrought out in the course of untold ages of variation and selection. It has to be admitted, however, that what goes on is more complicated than the working of any machine known to man; that mechanical interpretations of such functions as excretion and respiration have had to be abandoned from time to time because they did not cover the facts; that heredity, variation, and development seem facts *per se*; and that the organism is strangely autonomous. For these and similar reasons there is periodic reaction from mechanism to vitalism.

"Vitalism assumes that the intimate processes are guided or controlled by an influence which is manifested only in living organisms, and which acts in a manner wholly different from anything known in the inorganic world."

To Dr. Haldane the theory of vitalism is no more acceptable than that of mechanism. For if a vital principle controls what goes on in the organism, can it do so without a breach in the conservation of energy; and if it guides, how does it know how to do it? The hypothetical vital principle is unproved, unintelligible, and useless. In this chapter, the answer to Driesch's argument from embryonic development seems to us very far from clear.

The second lecture contains a criticism of the mechanistic theory. It has been useful in stimulating research, but it is inadequate for the redescription of what is essentially vital. A minute increase in the hydrogen ion concentration of the blood induces an intense activity of the respiratory centre, but we do not know the chain of events between the stimulus and the response.

"In the case of stimulus and response there is in reality no experimental evidence whatsoever that the process can be understood as one of physical and chemical causation."

Or what are we to make of the "recovery of functional activity after destruction of centres or nerve paths on which this activity normally depends?" Moreover, the fact is that "physico-chemical explanations of elementary physiological processes are as remote as at any time in the past." Even if we could picture the vast assemblage of delicately-adjusted cell-mechanisms, keeping themselves in working order year after year, keeping in exact co-ordination with all the other cell-mechanisms, and so on, how can we conceive of this condensed into a germ-cell, uniting with another germ-cell, and then developing afresh. And the difficulty of thinking mechanically of reproduction recurs when we picture the continual renewal of cells and plasm within the body, the ceaseless work of maintaining a structural and functional specificity. Dr. Haldane concludes that "the phenomena of life are of such a nature that no physical or chemical explanation of them is remotely conceivable." In speaking of the mechanistic view of the germ-plasm, the author says, p. 58: "On the one hand we have to postulate absolute definiteness of structure, and on the other absolute indefiniteness." But it seems to us that the word indefiniteness is here used in a sense not inconsistent with definiteness, namely, in reference to the number of divisions that may occur. If we understood *one* division, we should not boggle over an indefinite number of them.

In his third lecture Dr. Haldane turns the tables on the mechanists. The physical and chemical concepts are, after all, but working hypotheses; the notion of a real and self-existent material universe does not survive Hume's criticism. In any case, when we pass to the world of organisms we need new concepts, especially that of the living organism, a specific entity, actively maintaining and reproducing its individual structure, with functions which are determined in definite relation to the whole unified

activity, an autonomous active whole. "The conception of organism is a higher and more concrete conception than that of matter and energy." In the ruins of the atomic theory, it is already being extended to the whole of nature. "We are not seeking to reduce the organic to the inorganic, but the inorganic to the organic." To us it appears unnecessarily dogmatic to assert that "there is not the remotest possibility of deriving the organic from the inorganic." Would it not serve to say that we cannot think of the origin of organisms from the inorganic world, if the reality of the latter is supposed to be exhausted by the current concepts of chemistry and physics? And are we not bound in fairness to admit that while the physical and chemical formulæ need not be regarded as exhausting the reality of the inorganic world, they serve for certain practical purposes exceedingly well, and must bear a definite relation to reality since we successfully stake our lives and our reputations (as scientific prophets) on their validity.

The fourth lecture finds a philosophical foothold in the recognition of personality as the central fact in the world. We may consider a man as a material system weighing seventy kilogrammes, and this partial and abstract way of looking at him is sometimes of use; we may also consider him as an organism, maintaining specific structure and activity, and this is also useful; but we get nearest the real man when we know him as a person. Personality—mere organism—matter: "the relation is simply one of different degrees of nearness to reality in the manner in which phenomena are described." But personality is more than an individual concept; "the personality of any individual is the spiritual inheritance of ages; the individual participates in the life of the species; personality includes within itself our whole universe. We know extremely little about what we call matter; "the reality behind the appearance of a physical world has and can have no existence apart from personality." And thus, as the physiologist in his first two lectures sought to lead us away from the error of mechanism, so the philosopher in the last two seeks to lead us to the conclusion that the world, with all that in it is, is a spiritual world. But the realist has also something to say for himself!

FUELS FOR POWER PRODUCTION.

Fuel: Solid, Liquid, and Gaseous. By J. S. S. Brame. Pp. xv+372. (London: Edward Arnold, 1914.) Price 12*s.* 6*d.* net.

MR. BRAME'S treatise is one of a long succession of books dealing with the general subject of fuels, but in view of the wonderful rapidity with which processes relating to fuel manufacture and its preparation are changing, and of the new uses to which the fuels are put when made, there is ample room for new-comers. The author writes specially for the large class of readers to whom power production is of chief importance, and he has produced a volume which will be an extremely valuable addition to their bookshelves.

The subject divides itself naturally into three divisions—solid, liquid, and gaseous; Mr. Brame discusses each separately, and adds a section on fuel analysis, calorimetry, and the control of fuel supply. Under the title "Solid Fuels" are included wood, peat, coal, coke, coalite, and the minor fuels; liquid fuels include petroleum and tar oils with their derivatives, together with alcohol. The longest section, that on gaseous fuels, contains an account of the manufacture and properties of water gas, of Siemens and Dowson gas, and of blast-furnace and coke-oven gases.

Well-informed as the author appears generally to be, he makes a strange omission when discussing the velocity of flame propagation in an explosive mixture—the stranger in a book bearing specially in view the production of power—in that he omits reference to the striking influence on this velocity of "turbulence" in the gaseous mixture. As Clerk has shown in the reports of the Gaseous Explosions Committee, turbulence is of first importance in influencing the velocity with which the explosion spreads to all parts of the gas, and that except for this no high-speed gas or petrol engine would be able to run at the speeds necessary for their effective use.

The Bonecourt system of surface combustion is described briefly, but perhaps as fully as can be expected in a book dealing with fuel itself rather than with its manner of use. The author compares the 90 per cent. efficiency of this system when applied to the heating of steam boilers with the 55 to 65 per cent. which is usual with coke-oven or blast-furnace gases used in the older way. This improved method of steam raising is potentially of great practical importance, and we are glad the author has found space to include a number of interesting efficiency figures.

Under the title "Economic Aspects of Liquid Fuel" the author discusses the present situation in which fuel users are placed owing to the rapid change in price. He reiterates the relative insignificance of the annual oil output compared with the coal output, and affirms his belief in the possibility and the economic advisability of the production of alcohol for power uses. This is one of the best parts of the book, and the author is assuredly correct in saying of industrial alcohol:

"Its adoption would give encouragement to agriculture; it would provide a national weapon to fight artificial (or economic) shortage of other fuel for internal combustion engines; indirectly it would encourage the further development of a big and growing branch of engineering, the success of which is impossible without an assured supply of fuel at a reasonable cost."

H. E. W.

MODERN PRACTICE IN THE EXTRACTION OF METALS FROM THEIR ORES.

The Metallurgy of the Non-Ferrous Metals. By Prof. W. Gowland. Pp. xxvii+496. (London: C. Griffin and Co., Ltd., 1914.) Price 18*s*. net.

THIS book is a most valuable addition to the series of metallurgical text-books published by Messrs. C. Griffin and Co. It gives in a concise but wonderfully complete form the up-to-date practice in the extraction of the following metals from their ores: copper, lead, gold, silver, platinum, mercury, zinc, cadmium, tin, nickel, cobalt, antimony, arsenic, bismuth, and aluminium. Under the heading of each metal are considered (1) its physical and chemical properties; (2) the alloys of which it is the chief constituent; (3) the composition and applications of commercial brands; (4) the chief ores and processes by which the metal is extracted from them and rendered suitable for industrial or other purposes; (5) the principles and conditions on which the success of these processes depends; and (6) examples of actual practice in important extraction works. The author states that special attention has been given to the metallurgy of gold, silver, copper, and lead, which undoubtedly constitute the most important members of the above group. This statement is thoroughly justified, for, so far as we have been able to ascertain, every important modern successful process has received attention.

In writing this book the author has had in view not only the student engaged in a course of metallurgical training, but also the man who is actually dealing with practical problems; and he is particularly well qualified to present both these important aspects of the subject. It is perfectly true, as he points out, that much valuable information with regard to modern metallurgical practice may be found in technical periodicals and the proceedings of societies. Those who have the opportunity of consulting such publications will, we think, find his critical comparisons of similar processes of great value, while to the man whose time is limited or who has no technical library within reach the book will be one of the most valuable that has ever been published. The clear and full table of contents enables a reference to any particular process, and, indeed, to any special feature of it, to be readily made.

The author writes with rare, indeed, almost unique, knowledge of the metallurgy of copper, and his mastery of the subject cannot be better illustrated than by mentioning that in the compass of eighty-one pages every important aspect is dealt with. The ore now being pyritically smelted at the Tennessee Copper Co.'s works at Copperhill runs rather lower in copper than the figure 2 to 2½ per cent. mentioned by him (p. 100); it does not exceed 1·9 per cent., and is tending to become even lower in grade. We think that the Chilian Mill might have received more attention than the three lines devoted to it on p. 208. At the present time almost, if not quite, all the Cripple Creek gold ores are reduced by Chilian mills, the Stamp Mill having been practically superseded in this district. Harker's value of 1710° C. is given for the melting point of platinum. It is now generally recognised that this figure, which was obtained on the thermo-electric scale by extrapolation, is too low. The value 1755° C. quoted recently by the Bureau of Standards is probably much nearer the true figure.

SCIENCE AND INDUSTRY.

The Co-operation of Science and Industry. By S. R. Illingworth. Pp. 91. (London: C. Griffin and Co., Ltd., 1914.) Price 1*s*. 6*d*. net.

THIS little book has a special interest at the present time. The author deals with the history of science as applied to industry, and while avoiding any violent diatribes against the supineness of the British manufacturer, he points out what may be done to recover the supremacy of our trade. The employment of more scientific men in most of our works is strongly advocated, not only of the higher class of research men, but also of the class of routine analysts. The first class is required to devise new processes along scientific lines, to discover uses and outlets for bye-products, and always to be on the look-out for methods for gaining the maximum yield of finished products at the minimum of cost.

"To many business men the employment of such a man may appear a luxury; almost a gamble! The few that have such men are only employing them for some specific object, and maybe will rest content when that object is attained. Such an attitude is fatal."

If the German manufacturers had been content to take this line, the magnificent industries which they have built up would certainly not have come into existence. We have now, at this moment, an opportunity of recovering the ground we have lost.

The Government Committee on the Chemical Trades is composed of men who will command the confidence of everyone, and their recommendations will have great weight. It must not be forgotten, however, that nearly all trades would be benefited by scientific help. The attitude of mind induced by scientific education is just the one required for the successful development of a business. If the manufacturers as a whole would realise this, they would see to it that their sons or those who are to carry on their business, have a thoroughly good scientific education, such as may now be got at many of the Universities and technical colleges in the country. It is not the classical or the modern side of our schools which is going to supply the successful manufacturer of to-morrow, it is the side where a man is taught to bring all his useful knowledge to bear on the achievement of success. Mr. Illingworth's book is the most successful attempt which has been made to explain the situation, and we believe that if the Government would send a copy of the book to each manufacturer in the country, the cost would be a mere nothing compared with the effect which would be attained.

OUR BOOKSHELF.

A Little Book on Map Projection. By Mary Adams. Pp. viii + 108. (London: George Philip and Son, Ltd., 1914.) Price 2s. net.

It is very satisfactory to find that at the present time care is being taken that the principles of map projection are being studied as soon as the use of maps is seriously undertaken. At one time this part of their subject was much neglected by geographers, and left to those whose mathematical aptitude was especially developed. In this book Miss Adams aims at meeting the needs of the secondary and the higher elementary schools; and in clear and simple language sets forth the difficulties of an adequate cartographical representation of the earth's surface. Simple explanations are given of the principal types of projection, and then the distortion of the original spheroidal surface when it is represented on a plane surface is explained, and the compromises which have to be adopted are set forth. After this preliminary exposition, into which no mathematics enter, there follows a more detailed discussion of the principal zenithal, conical, and cylindrical projections, as well as certain special projections. These are illustrated by diagrams, and the explanation which is given of each should enable anyone to obtain a clear idea of the essential character of each kind.

A short appendix gives a more mathematical account of Mercator's, the Zenithal, and Mollweide's projection, but with this exception no demand of any but elementary mathematical knowledge is made upon the reader.

A short bibliography, which might be usefully extended by the inclusion of some well-known German and Italian works, shows the student where he may find a more advanced treatment of the subject. The book is carefully written and well adapted to those for whom it is intended, and, while it cannot give them that complete knowledge of the subject which mathematical treatment alone can supply, it will pave the way to an intelligent appreciation which is of the utmost value to all who use maps.

Chemical Engineering: Notes on Grinding, Sifting, Separating and Transporting Solids. By J. W. Hinchley. Pp. viii + 103. (London: J. and A. Churchill, 1914.) Price 2s. 6d. net.

In this series of articles, reprinted with some additions from the *Chemical World*, Mr. Hinchley provides, for the use of students intending to take up chemical engineering, a concise and practical outline of a subject of wide scope. The articles are illustrated with seventy sketches and diagrams, and their thoroughly practical character will be much appreciated by students of this branch of technology.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Fizeau's Experiment and the Principle of Relativity.

It is well known that the principle of relativity gives for the velocity of light in a moving medium the expression

$$\frac{c}{\mu} + kv, \text{ where } k=\left(1-\frac{1}{\mu^2}-\frac{\lambda}{\mu}\frac{\delta\mu}{\delta\lambda}\right)$$

where v is the velocity of the medium, and c/μ is the velocity when at rest. The repetition of Fizeau's experiment by Michelson and Morley gave for water the value $0{\cdot}434 \pm 0{\cdot}02$ for the coefficient k, whereas the value of the theoretical coefficient, taking the known values of μ and λ for sodium light, is $0{\cdot}451$, which is well within the limits of the possible error.

The experiments of Gutton (*Journ. de Phys.*, ii., p. 196, 1912) show clearly that in the case of a very dispersive medium like carbon disulphide the velocity of propagation of nearly homogeneous light is the group velocity, and not that of an absolutely monochromatic train of waves. If this is universally true, as Lord Rayleigh and Gouy have predicted, then in the expression for the convection-coefficient k, the symbol μ must stand for the ratio of the velocity of light in free space to the group velocity. If we call the ordinary coefficient of refraction μ_0, we have

$$\mu=\mu_0\left(1-\frac{\lambda}{\mu_0}\frac{\delta\mu_0}{\delta\lambda}\right);$$

neglecting the square of $\frac{\lambda}{\mu_0}\frac{\delta\mu_0}{\delta\lambda}$ (*i.e.* of $0{\cdot}014$) and terms of the same order, we have

$$k=1-\frac{1}{\mu_0^2}-\frac{\lambda}{\mu_0}\frac{\delta\mu_0}{\delta\lambda}-\frac{2\lambda}{\mu_0^3}\frac{\delta\mu_0}{\delta\lambda}+\lambda\frac{\delta}{\delta\lambda}\left(\frac{\lambda}{\mu_0}\frac{\delta\mu_0}{\delta\lambda}\right)$$

If we take the dispersion-formula of Ketteler and calculate the values of the two last terms in this

expression, we find that they are respectively $+0.016$ and $+0.022$, so that the theoretical value of k becomes $6.451+0.038$, that is, 0.489. This even is in worse agreement with the experimental value 0·434 than the value 0·451 usually given, but a consideration of the experimental conditions shows that the value to be deduced is in reality 0·492, which is in excellent agreement. The argument will shortly be published in full. E. CUNNINGHAM.

St. John's College, Cambridge, October 14.

Flint Fracture.

IT is to be regretted that the letter of Mr. Reid Moir in NATURE of September 24 has received no reply. If chemists, mineralogists, petrologists, and physicists could have been made to realise the fruitful fields for profitable and far-reaching research opened to them by this subject, our knowledge would be in a very different state to-day, and many of the contentions and mysteries would be replaced by demonstrable facts.

In all text-books we see descriptions, or references, to lydite, the touchstone of the goldsmith, and in museums and collections we see specimens bearing this name; all kinds of origins are claimed for it; sedimentary, volcanic, metamorphic, and one has even seen meteoric. In text-books we see descriptions of the pebbles in the Blackheath beds; we are told they are pebbles of flint still retaining their original black colour. As a matter of fact, they are not black flint; they are now of various colours. It is their surface that is black; the metamorphosed portion may not be thicker than tissue paper, but other examples can be found upon a sea-beach where it is an eighth of an inch thick, and from this onward until the whole is metamorphosed, and we have the jet-black mineral, which does duty under the name of lydite!

Just one more example. The same text-books describe the beautiful "Egyptian jasper"; some say the locality from which this has been derived is unknown; others venture to suggest one. One of the many metamorphoses of flint is jasperisation. We see this commence on the surface of flints (one of the things called patination); this proceeds in intensity and centrewards until the whole substance is altered, and we have the rich mottlings of yellows and browns, quite equal to those of Egypt. The so-called Egyptian jasper may be a metamorphosed British flint.

Mr. Reid Moir refers to lines radiating from the point of percussion on the fractured face of a flint; here is something for the physicist; they certainly are not "fissures," but rather lines of force (closely connected with facetted cones and stellate fracture). The best place to see these, and study them, is in asphalt or pitch. So long as the "fracture-" or "flaking-plane" maintains itself constant, *i.e.* in relation to the striking-plane, they remain fairly simple. If, however, the fracture-plane resolves, or even undulates very deeply, then a very remarkable phenomenon obtains, and the lines end in a row of cones just over the escarpment, looking like a row of pointed tents with a rope passing from the centre pole of each to the point of percussion!

The last weeks of Sir John Evans, before he took to his final bed, were spent in studying a large collection brought together to put the whole subject of lithoclasiology on a scientific footing. His last words to the collector were: "Promise me that if I do not pull through this operation, you will lose no time in publishing all this. I am certain that this is where we ought to have started sixty years ago, and no real progress will be made until we start here."

If we take half a dozen pieces of flint of exactly the same shape and size, and apply exactly the same force, administered in exactly the same manner, and of exactly the same intensity, the results may be very different in each case. Before we can argue from the effect to the cause, we must know something about the nature of the object acted upon. We must start with the origin and nature and varieties of silica, the various metamorphoses and molecular rearranging to which each variety is subject, and how each variety, in each state, responds to dynamic agency, whether administered by nature or man.

So also when we come to dynamics we must study every mechanical possibility, single them out, and name them, so that every observer may know what the other is speaking about. There must be no "peculiarities known only to the student," and "no features known only to myself." Each phenomenon must be capable of separate study, and receive a special name, so that all understand what they are talking about.

There are few who appreciate the splendid work which Mr. Reid Moir has been doing more than myself, but I am quite sure that if he were to restart the subject, on the lines here indicated, in a very short time he would regard the points he raises with very different eyes. W. J. LEWIS ABBOTT.

8 Grand Parade, St. Leonards-on-Sea.

Filtering Power of Sand.

THE letter of Mr. C. J. Watson in NATURE for October 15, recommending that "Nachtblau" (night-blue) should be used for experiments on adsorption by sand, leads us to point out that so far back as 1909 we demonstrated before the International Congress of Applied Chemistry (Section IV.B, p. 7) the striking experiment in which a solution of this dye issues perfectly colourless after passing through a column of purified sand. Since this date the experiment has been frequently used for demonstration purposes at lectures on adsorption by ourselves and others.

We showed in 1909 the remarkable quantitative relations existing between the weight of sand and the weight of dye absorbed; each degree of fineness of the sand is characterised by a remarkably sharp coefficient of adsorption, the value $\frac{\text{weight of dye adsorbed}}{\text{weight of sand}}$ being constant for the same sand to the sixth decimal place (in one series, for example, values 0·000147 to 0·000148 being obtained). The relation of these experiments to the general theory of dyeing was dealt with in the paper cited, and also in a later communication to the Society of Chemical Industry (1912, vol. xxxi.).

Scientific Societies and the War.

SUGGESTIONS have recently been made that certain of our scientific societies should suspend their meetings for the present, on the ground that "it is difficult to take an interest in such things just now." To those who share this feeling, it may be worth while to point out that, as already recorded in NATURE, the Académie des Sciences held its usual meeting Paris on September 7. Under that very date, in the *Times* review of the war for September, we find the entry, "Germans reach the extreme point of their advance." Among our gallant Allies, at all events, "le tour d'ivoire ne se rend pas." W. T. CALMAN.

British Museum (Natural History), October 16.

THE X-RAY SPECTROMETER.

IT is now well known that a homogeneous pencil of X-rays is capable of reflection by a crystal provided that the rays are directed upon the crystal at the proper angle.[1] If λ is the wave-length of the X-rays, d the spacing of the crystal planes, and θ the angle which the rays make with the planes, these quantities are connected by the relation $n\lambda = 2d\sin\theta$,[2] where n is an integer.

The object of the spectrometer is to determine the value of θ in any given case—that is to say, for a definite set of X-rays and a definite set of crystal planes. The results may be classified as follows: If we use different crystals or different faces of the same crystal, but keep the rays the same, we can compare the spacings of the various sets of planes. In this way we arrive at a knowledge of the relative positions of the atoms in the crystal—that is to say, we determine its structure.

If we use the same crystal always, but examine the angle of reflection of different homogeneous X-rays, whether from the same or from different sources, we have the means of comparing the wave-lengths of those rays. We can, in fact, analyse X-radiation in exactly the same way as an ordinary spectrometer analyses light.

The new instrument resembles the ordinary spectrometer in its general construction. To the collimator corresponds a set of narrow slits limiting a pencil of X-rays, which is directed so as to pass through the axis of the instrument. A crystal takes the place of the diffraction grating, and is mounted on a small revolving table. The crystal face or set of planes which is acting as reflector is made to contain the direction of the axis of the instrument, and the crystal is turned round the axis until the face makes the proper angle with the incident pencil. The reflected ray then enters a cylindrical ionisation chamber filled with gas which it ionises. The chamber takes the place of the ordinary telescope, and the measurement of the ionisation current by an electroscope corresponds to observation by eye or by the photographic plate.

In the drawing of Fig. 1,[3] which shows the arrangement of the apparatus in plan, Q is the antikathode of the X-ray bulb. The construction of the bulb is a little unusual in that the antikathode is placed perpendicularly to the kathode ray stream; the bulb can therefore be conveniently arranged so that the X-rays leave the antikathode at a grazing angle. The finer the angle which the rays make with the antikathode, the more nearly does the source become, effectively, a "bright" line; and the narrower the line the brighter it becomes, because the "whole illumination" given out in any direction by the spot on the antikathode is independent of the direction. The law followed is not that of the illumination by a surface of uniform luminosity, but rather that of the illumination due to a number of separate sources lying in one plane, each radiating uniformly in all directions. It corresponds to the case described by Rutherford, in which α rays are radiated from a uniform thin sheet of radio-active matter spread upon a plane surface (*Phil. Mag.*, August, 1906). The arrangement is of considerable value; the more nearly is the source a bright line parallel to the slit, the "purer" is the spectrum.

The X-ray bulb is enclosed in a wooden box heavily coated with lead. The object is to protect not merely the observer but also the sensitive apparatus. The slit through which the rays pass is only a few millimetres long and very narrow, sometimes no more than a tenth of a millimetre

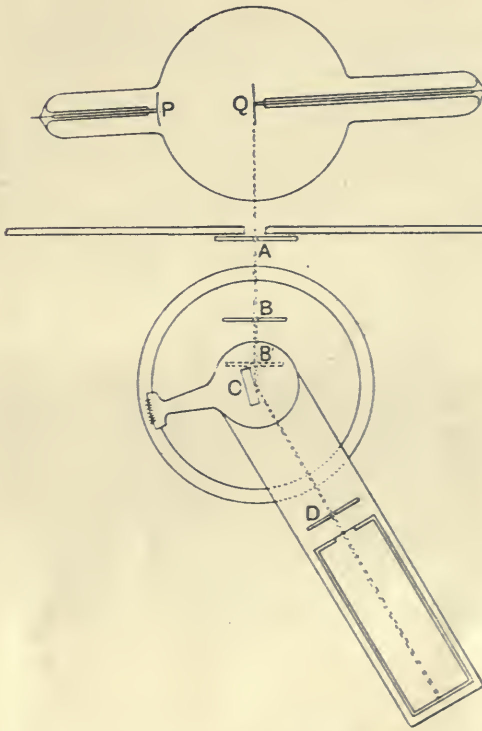

FIG. 1.—X-ray spectrometer. Plan of general arrangements.

wide. Only a small fraction of the pencil that emerges is reflected in the best of circumstances, so that it is necessary to screen off all stray radiation with great care; it must be small in comparison with the radiation which is to be measured. The side of the box is shown on the left of the photograph of Fig. 2. Adjustable slits are placed at A where the rays leave the box, and again at B, the second slit being also capable of a movement which brings it close up to the crystal, as at B′. The crystal is shown at C, and a third slit, D, is placed just in front of the ionisation chamber.

The ionisation chamber is marked I in Fig. 2. It is a cylindrical brass chamber 15 cm. long, and

[1] A summary of the principles on which this experiment is based, and of the progress of its development may be found in NATURE of July 9, 1914, p. 494.

[2] *See* Proc. Camb. Phil. Soc., November 11, 1912, or Proc. Roy. Soc., April 7, 1913.

[3] From a book now in the press, to be published by Messrs. G. Bell and Sons.

is filled with some heavy gas, so that the ionisation current may be as large as possible. Sulphur dioxide is convenient in many cases, but methyl bromide is much better for rays which can excite the bromine X-rays. Such rays are, for example, given off by antikathodes of silver, rhodium, or palladium, the latter two of which have been much used in the determination of crystal structure, because they give off intense homogeneous rays and also stand up well against the bombardment by the kathode stream. The chamber I is insulated and maintained at a high potential, which drives any ionisation on to an internal electrode. The latter is connected by a fine wire which passes down inside the metal shield WW to the gold leaf electroscope (Wilson pattern) within the shield E. The connection with the electroscope terminal is made at a point lying on the axis of

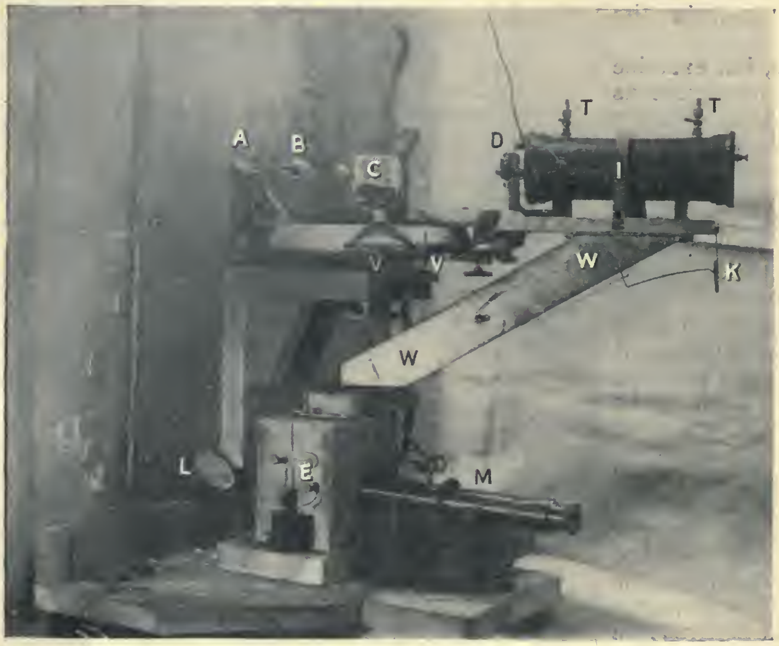

FIG. 2.—Photograph of X-ray spectrometer.

the spectroscope, so that the ionisation chamber I, the casing W, and the connecting wire may all revolve together about the spectrometer axis without straining the connection. The shielding is made solid and strong: it is necessary that the electrostatic screening should be perfect, and the electroscope must be protected from draughts which may cause changes in temperature.

The gold leaf is illuminated by reflection from a mirror L, and viewed through a microscope M. A strong X-ray reflection will cause the leaf to move twenty or thirty scale divisions in a second.

The angular positions of the crystal and the ionisation chamber are read from verniers at V and V'. Observations can easily be made to half a minute of arc, and much finer work could certainly be done, if it were required. The actual angle of reflection can be measured with an accuracy higher than can be reached in our knowledge of certain other data used in some of the calculations; for example, the actual weights of the atoms.

Crystals are often very imperfect in construction, consisting rather of a conglomerate of smaller crystals in more or less imperfect alignment. It is interesting to observe that the spectrometer may be used in ways which almost completely overcome the evil effects of the imperfections. In the case of a very perfect crystal like the diamond, the slit at A is not used, but B is set very fine; D is wide open. The crystal is slowly turned by a tangential screw attached to the revolving table, and there is no reflection at all outside very narrow limits. The angle of maximum intensity of reflection can easily be determined to a few seconds of arc. But a crystal of rocksalt cannot be treated in this way. It is best to set A and D fairly fine and not to use B at all. On account of certain most fortunate geometrical considerations, a homogeneous pencil of some divergence issuing from A and reflected at various points on the crystal face is brought to a line focus at D, provided that A and D are at equal distances from the crystal (Proc. Roy. Soc., lxxxviii., p. 433). A perfect crystal would reflect such a pencil only along a certain vertical line on the crystal face; but a poor crystal, like rocksalt, at a number of separate points on the face. Even crystals which are scarcely recognisable as such may be treated by this method.

The higher orders of spectra, that is to say, reflections at angles for which n has a large value, three, four, or five, naturally give more accurate values than lower orders, though the intensity diminishes rapidly as n increases. The "resolving power" increases even faster than n, since $d\theta/d\lambda$ is easily seen to be equal to $\tan\theta/\lambda$, which becomes very large as θ approaches the value $\pi/2$. For example, a certain pair of lines emitted by a platinum antikathode are separated by thirty minutes of arc in the first order spectrum reflected by the cleavage face of the diamond, but in the third order spectrum they are two and a half degrees apart.

With a little practice it is quite easy to pick up the reflected X-ray. While the search is being made the slits are opened wide; as soon as the reflection is observed the slits are made narrow, and accurate measurement is then possible. It is a comparatively simple matter to find the angles of reflection of rays of given quality in the various faces or sets of planes of a crystal. The greater difficulty arises in the geometrical interpretation of the results.

THE SEA FISHERIES AND THE WAR.

It appears possible that the British sea fisheries will suffer from the effects of the war more, perhaps, than most other national industries. Already a large part of the North Sea is closed to trawl fishing, and it may be that before long all this area will become a *mare clausum*. Since we have taken rather more than 60 per cent. of our fish supply from this sea in recent years the loss to the fishing industry is serious. The actual war losses, so far, have been insignificant, but when to these are added the loss to the national food supply of the vessels and men now engaged in mine-sweeping, the disturbance to the industry which must result from the shifting of the fishing fleets to other open waters, and the loss of the Continental markets for cured herrings, the total loss will be sufficiently great. Add to this the incalculable loss which scientific research must bear in the suspension of the international fishery investigations, and we have very much to lay to the blame of German world-politics. The co-ordinated scheme of fishery observations carried on up to last July by the maritime powers of Northern Europe was the laborious result of more than a dozen years' negotiation; probably no one then engaged in it will live to see its resumption.

Upon such industrial and scientific ruin we must endeavour to build anew, and it is fortunate that even before the war the way had been indicated. Scientific research is unlikely to suffer permanently, inasmuch as those engaged in it will turn now to domestic rather than international problems, and that this was desirable, even apart from the war, the recently published report of the Inshore Fisheries Committee indicated. It can scarcely be doubted that the increased exploitation of the lucrative fishing grounds outside the North Sea will compensate, to some extent, for the closure of that area; the enterprise of the English fishing-vessel owners has already been so marked that we need not fear this temporary set-back to the industry. Also the formation of the Fisheries Organisation Society, as the result of the Inshore Committee's report, and with the support and approval of the Board of Agriculture and the Development Commission, was a most fortunate thing, as events have turned out. This body proposes to undertake propagandist work among the inshore fishermen, and generally to take all possible steps to develop to their fullest extent the very considerable natural resources of the shallow seas and foreshores. We cannot doubt that as the result of active and far-seeing measures foreshadowed in the report to which we refer these resources may become a huge national asset in the way of amplifying the food supply and providing productive employment.

Lastly, there is the great East Coast herring fishing and curing industry—one which has already suffered greatly. It is here that propagandist measures are most urgently required, with, we suggest, some State assistance for the holding in this country of the stocks of salted herrings which might yet be obtained in what remains of the present season. Official and semi-official pamphlets and articles already published by the Board of Agriculture and Fisheries and the National Sea Fisheries Protective Association ought to have a wider circulation in order that they may familiarise the people, even well-to-do people, with the enormous supply of excellent and nutritious food in the shape of salted herrings, cod, ling, etc., which is available to the United Kingdom in times of stress. Some education for the British housewife and cook, and some persuasion that the cheapest kinds of fish are little inferior in taste, and not at all in nutritive value, to the dearest kinds are required; and the evening schools and public lectures of the coming months ought to be utilised for these purposes.

It is difficult to estimate the increase of value which industrial exploitation might confer on the raw materials of the inshore fisheries, but one could scarcely err in exaggerating this value. An enormous quantity of shrimps, prawns, and crabs are sold in the fresh (or nearly fresh) condition; by potting or otherwise preserving these raw materials employment would be largely increased, the products would lose nothing of their nutritive value, and would become much more "tasty," while they would be more easily and widely distributed. Enormous quantities of sprats can be caught during the next winter; these are difficult to sell and distribute; in many places they are nearly worthless commercially, while they are nutritious and excellent food. Why should not they be "sardined," thus again enhancing their food value, and conferring employment?

Mussels and cockles can be taken round the shores of England, Wales, and Ireland in very large quantities. For some years past there has been a market for only a small fraction of the shellfish that could be so obtained. This has been the result, almost entirely, of the prejudice that has been set up against these molluscs because exceptionally they have been the means of disseminating epidemic disease. In some cases this fear has been exaggerated, in others it has been well founded, but there can be few cases in regard to which it is not possible to remove all danger by appropriate means. It is quite certain that mussels and cockles can deliberately be laid down and fattened in water which may be polluted by sewage refuse, and then cleansed from ingested micro-organisms by relaying in clean sea-water. Here, again, a national food supply of cheap and nutritious quality can be conserved and amplified by means which also confer unskilled employment upon those who are likely to require it. Also, scarcely any attempt has yet been made to "pot" or preserve in suitable ways these shellfish, but one cannot doubt that efforts in this direction might be highly successful.

There are other fisheries which might conceivably be developed by the fishermen and the manufacturers under appropriate stimuli—the very abundant sea crayfish (or Norway lobster), for instance, a crustacean which is not inferior, either fresh or "potted," to the lobster itself. Herrings might be tinned to a much greater extent than at

present. In all these cases the stimulus or suggestion may be made by the official, but it is evident that the hope of developments along these lines lies in the enterprise of the manufacturer. Preserving, curing, and tinning are operations demanding machinery and commercial aptitude and resources. Perhaps the genius of British commerce lies rather more in business organisation, distribution, and the like, than in actual production—at least, such must have been its tendency in times of peace and prosperity. But we have seen that in such a time of national stress as that through which we are passing purely personal commercial interests have been subordinated—the price of fish, for instance, would doubtless have been higher than it is now but for a self-denying ordinance on the part of the distributing trade. National emergency may well be the stimulus to increased development of the sea-fisheries if only the public will back up efforts on the lines we have indicated. J. J.

THE TOTAL SOLAR ECLIPSE EXPEDITION TO HERNÖSAND, SWEDEN.

IT had originally been arranged by the Joint Permanent Eclipse Committee of the Royal and Royal Astronomical Societies that a party consisting of Prof. Fowler, Mr. Curtis, and myself, with Major Hills and Father O'Connor as volunteer observers, should proceed to Kiev in Russia to observe the total solar eclipse of August 21. However, difficulties having arisen with the Russian Government, with regard to the admission of Father O'Connor and myself into the empire, on account of the categorical law excluding Jesuits, it was found necessary to divide the expedition, and ultimately a party consisting of Father O'Connor, Mr. G. J. Gibbs, Mr. E. T. Whitelow, and myself, proceeded to Hernösand in Sweden. Leaving Hull on July 28, and Stockholm on August 2, we arrived at our destination on August 3.

Through the kind offices of Prof. B. Hasselberg, of Stockholm, the head of the Swedish eclipse committee, and the assistance of Father Wulf, of Valkenburg, who with his assistant, Father Rodés, was proceeding to Hernösand, we secured an excellent site for our instruments in a field adjoining the Technical School. Not only so, but the rector of the school, Herr Tham, with extreme kindness and courtesy, placed the whole establishment, with well-equipped laboratories, dark room, mechanical and carpenters' shops, practically at the entire disposal of the astronomers of the two parties.

Father Wulf erected his apparatus in a large lecture room facing due south, and Father Rodés had a fine coronagraph mounted equatorially in an adjoining portion of the grounds. Father Wulf made successful observations of the exact duration of totality, and the times of second and third contacts, by means of an Elster and Geitel potassium photo-electric cell. This formed one arm of a Wheatstone bridge and was balanced by a resistance of several megohms, the resistance of the other two arms being furnished by those of the battery of many cells which supplied the current to the electrometer. The difference of potential, due to the ionisation of the helium and argon contained in the cell, with a corresponding alteration in its resistance, caused by the variation in the intensity of the light falling on the face of the cell, affected a thin wire, 1/500-mm. thick, in the special electrometer invented by Father Wulf, which was displaced laterally. These displacements were recorded on a suitable drum with ample scale on the photographic film, which was clock-driven. A thin wire attached to a pendulum beating seconds passing in front of a source of artificial light gave the time scale.

Our own equipment (Fig. 1) consisted of three coronagraphs of 20 ft., 30 in., and 12 in. focal lengths, and a large spectrograph of the Littrow form. The three coronagraphs were mounted in echelon in front of a 16-in. cœlostat, being placed

FIG. 1.—The eclipse instruments, Hernösand.

in the azimuth of sunrise. The same cœlostat also supplied a beam of light to a 3-in. Cooke lens, which projected an image of the sun $4\frac{1}{4}$ in. in diameter on a graduated screen of ground glass, so as to obtain the angles subtended by the cusps at the sun's centre 10 minutes, 5 minutes, and 10 seconds before totality. This instrument was mounted above the 20-ft. coronagraph, so that Father O'Connor, operating the coronagraph, was also able to give the signals at the stated times before totality. The 30-in. and 12-in. coronagraphs were under the charge of Mr. Whitelow, who also made exposures before and after totality with a Zeiss single Protar lens of 14-in. focus, working at $f/16$. This camera was mounted on a tripod with wedge head cut to the latitude of Hernösand. He obtained photographs of the moon projected on the corona 30 seconds and 1 minute after totality. The optical parts of the Littrow spectrograph consisted of a single dense glass prism, 7-in. edge and angle 40°,

a 6-in. lens of 98 in. focal length, and a 6½-in. flat mirror. A Grub cœlostat of 8-in. diameter supplied a beam of light to a 5-in. Alvan Clarke lens of 7 ft. focal length, which formed the sun's image on the slit.

With the assistance of the town electrician, Herr Helenius, leads were run from the electrical plant in the technical school to operate an arc-lamp with iron poles, the pressure being 110 volts and the current 12 amperes. An auxiliary lens and a diagonal prism, which could be pushed backwards and forwards as required, formed the image of the arc on the slit. The slit could be covered with a plate of zinc having a horizontal aperture 1/10-in. in width, so that the comparison spectrum could be placed over the position occupied by the image of the dark moon. Owing to the skill and energy of Mr. Gibbs, the engineer to the party, the instruments were all erected, the cases being utilised as bases, and adjusted, by Monday, August 17, on which day drills were commenced. We were assisted by students of the technical school under the direction of Mr. Askling, the master of mechanical science. An eclipse clock, designed by Mr. Gibbs, was also erected, a large hand circulating round the dial once in 129 seconds, the computed duration of totality. Its face was lit up by an electric lamp.

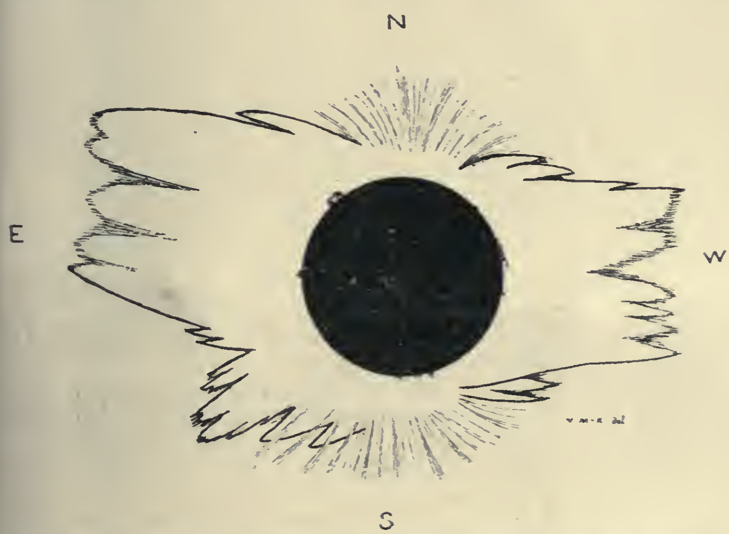

FIG. 2.—Main features of the Solar Corona of 1914, August 21, roughly outlined from photographs taken with the 20-ft. coronagraph at Hernösand.

The purity of the atmosphere at Hernösand was remarkable, but there was a very considerable amount of cloud on every day, except one, during the days preceding the date of the eclipse. The barometer was high with a persistent north-west wind, accompanied by a variety of types of weather. On the evening, however, of August 20, the wind changed to the south-east, and a beautiful night heralded the perfect weather conditions for the eclipse. The programme settled for me by the Joint Permanent Eclipse Committee was to obtain large scale photographs of the solar corona to show detail, and smaller scale pictures to show the extension. With the spectrograph the coronal spectrum was to be photographed, principally in the red and yellow regions, and if possible a comparison spectrum of the iron-arc was to be placed on the plate.

About half-past eleven on the morning of the eclipse a goodly number of spectators, dressed in their best clothes, assembled in the field near the site of the instruments, and watched the partial phases through dark glasses. In contrast to the demeanour of the spectators in the eclipse expedition to Vinaroz in Spain in August, 1905, they were quite undemonstrative, even when the magnificent sight of the corona in a perfectly dark sky was presented to their gaze. For certainly it was a magnificent spectacle, enhanced by the appearance of the planet Mercury brilliantly shining to the north-west limb of the sun, and Venus near the south-east horizon. To the naked eye the most striking features of the corona were a long fish-tail streamer on the west limb of the sun, and a spreading mass of streamers on the east limb, the salient phenomena being a streamer on the north-east, another shorter streamer south-east, and a long horizontal streamer, less luminous than the other two, placed equatorially. The prominences were not visible to the naked eye; they were seen projected on the slit, and a very fine arched prominence is shown in the north-east quadrant in the photographs. Five large scale photographs were secured with the 20-ft. coronagraph, with exposures of 4, 10, 25, 7, 3 seconds respectively. These show a great amount of detail, including beautiful sheafs of polar rays, prominences, and several crossing and interlacing streamers. The main features are shown in the accompanying outline drawing (Fig. 2), made from some of the negatives by Mr. W. McKeon. With the 30-in. Abney coronagraph, used in so many former eclipses, four photographs were secured, with exposures of 10, 50, 15, and 5 seconds, on plates bathed by Mr. Crowther, of Carlisle, so as to be not solarisable by over-exposure. These show the extension of the corona for fully two solar diameters. With the 12-in. coronagraph, working at $f/3{\cdot}5$, a single exposure was made for 95 seconds, on a Paget "Hydro" non-solarisable plate. This is a beautiful small scale picture, showing, probably, the full extension of the streamers.

With the spectrograph, while I made the exposures, Mr. Gibbs placed the sun's image correctly on the slit, and also took charge of the cœlostat. Several exposures were made at intervals of a few seconds on the tip of the cusps, seven minutes before and five minutes after totality. These mere lines of spectral light have so far not received adequate study. The comparison iron spectrum is on each plate, which

contains, besides, six exposures on the cusp tip. The spectrum of the corona shows very faint continuous spectra between λ4800 and λ6700, with several faint lines on each side of the comparison iron spectrum, and others further removed obviously belonging to the portions of the streamers intersected by the slit. The exposure of the plate was about 95 seconds, and that of the arc spectrum 4 seconds at mid-eclipse. The slit was placed just within the dark limb of the moon on the advancing side. A batch of freshly bathed Panchromatic B. plates was kindly forwarded to Hernösand by Messrs. Wratten and Wainwright.

On account of the war the programme for our homecoming had to be considerably modified. The plates were at once developed, and the instruments speedily dismounted, so that we might catch the first possible steamer from Hernösand to Stockholm. From Stockholm we came across land *viâ* Christiania to Bergen, whence we sailed to Newcastle. We had already crossed two Swedish mine fields under the escort of armed vessels, and our passage of the North Sea was no less adventurous and exciting. We were stopped by a British cruiser and warned of the presence of floating mines laid by the Germans directly in our intended course. The lifeboats were got ready, and the course was changed for one to the north of Scotland. A second cruiser pursued us, and, overtaking us, warned us of the danger ahead. Accordingly we came right down the Scotch and English coasts, and finally were convoyed into the mouth of the Tyne by three torpedo-boats.

A. L. CORTIE.

THE BRITISH ASSOCIATION IN QUEENSLAND.

Brisbane, September 4.

THE final session of the Australian meeting of the British Association for the Advancement of Science was held in Brisbane on August 27—September 1. It had been arranged that of the 320 visiting members of the Association, a party of one hundred should visit New Zealand after the close of the Sydney Session, and that the remainder should visit Brisbane, where the final official business would be transacted. Unfortunately the state of war in which Australasia in common with the rest of the Empire is involved, interfered somewhat with this arrangement. The cancellation of the New Zealand meeting caused a number of those, who would otherwise have gone to the Dominion, to express a desire to visit Brisbane instead. At the same time the utilisation of the R.M.S. *Orvieto* as a transport caused a number of people who had intended returning to England in her to shorten their visit to Australia.

As a consequence of these changes in *personnel* of the party which came to Brisbane the local

FIG. 1.—An excursion party of the British Association at a wood-chopping contest in the Australian bush.

arrangements suffered disorganisation to such an extent that the plans which had been formed had to be modified greatly, and fresh arrangements made in the four days immediately preceding the meeting.

The Brisbane party left Sydney on Wednesday, August 26, in two special sleeping trains. The visitors arrived at Wallangarra on the Queensland border in time for breakfast, at which and also at lunch they were the guests of the Queensland Government. At Wallangarra a change of gauge occurs, the New South Wales gauge of 4 ft. 8½ in. being left behind, and the narrow gauge of 3 ft. 6 in., which is common to all the Queensland railways, being reached. The party travelled from Wallangarra in two special trains, arriving at Toowoomba in time for luncheon and reaching Brisbane about 6 p.m.

The arrangements which had been made for the conveyance of the visitors to the homes of their guests worked very satisfactorily, and within eight minutes of the arrival of the trains the last of the visitors had left the station.

The reception room and post office were situated at the temporary university building, but unfortunately it was not possible to arrange for the lectures and addresses to be delivered there on account of the absence of any hall or lecture-room large enough to accommodate the audiences which were anticipated.

Two addresses were delivered on Friday morning in the Albert Hall. The first, which was officially described as the second part of the presidential address in Section M (Agriculture), was given by Mr. A. D. Hall, who chose as his subject "Tropical Agriculture." The hall was well filled with a large and appreciative audience; the local members were particularly interested in the subject, and it is hoped that the address will prove helpful in many ways.

It had been originally planned that the second address should be the second part of the presidential address in Section I (Physiology) on the subject of "Tropical Diseases," and on account of the peculiar local and climatic interest of the subject chosen much disappointment was felt in Brisbane at its unavoidable abandonment. In place of this Prof. E. W. Brown, of Yale, delivered an address on cosmical physics.

Two public lectures or discourses were arranged for Friday evening. Prof. Armstrong lectured to an interested audience in the Centennial Hall on the "Materials of Life." In his lecture he traced the building up of the simple compounds of carbon, hydrogen, oxygen, and nitrogen into the complicated compounds which are synthesised in the plant organism; also the breaking down of these under enzyme and other action during the process of digestion and the building up again from these relatively simple substances of the highly complicated products which are prepared in the animal organism. A vote of thanks was proposed by Prof. Steele, of Brisbane, and the subject was discussed by Prof. Bateson, who occupied the chair. The second lecture was held in the Albert Hall on the same evening. Sir Oliver Lodge occupied the chair, and Prof. Howe gave an interesting discourse on wireless telegraphy.

The meeting closed on Monday evening, when Sir Edward Schäfer gave a discourse on the subject "Australia and the British Association." At the conclusion of the lecture Sir Arthur Morgan, Lieutenant Governor of the State of Queensland, proposed a vote of thanks to the lecturer.

A citizens' lecture on decorative art in Papua was delivered by Dr. Haddon to a large audience in the Exhibition building, the Mayor of Brisbane, Alderman C. Jenkinson, occupying the chair. There were two garden parties given in honour of the visitors, one on Friday afternoon in Bowen Park by the Mayor of Brisbane, and another on Monday afternoon in the university grounds by the Government of Queensland, the Lieutenant Governor receiving the guests on behalf of the Government.

Photo.] *[Topical Press Agency.*

FIG. 2.—An excursion party of the British Association in the Australian bush.

The Senate of the University entertained the general officers of the Association, the presidents and ex-presidents of sections, and the foreign visitors at luncheon on Friday, August 28. The vice-chancellor, Mr. R. H. Roe, was in the chair, and proposed the health of the guests. This was replied to by the president, Prof. Bateson, in a

speech extremely inspiring and helpful to our young University.

The week-end was devoted to excursions, and amongst other places visited were the mines at Gympie and at Mount Morgan, the sugar and fruit-growing districts of Nambour and Cleveland, and the Prickly Pear infested country of the middle West, and the Prickly Pear experimental station at Dulacca. The officer in charge of this station is Dr. Jean White, who at present has more than 2000 experimental plots under investigation, and the object of whose work is to ascertain the best means of exterminating the pest.

After the close of the Brisbane session, the party separated, some returning to Europe by way of America, others through Java and India, and a large number of the party travelled by the mail route through the Suez Canal.

[One of the week-end excursions during the visit of the British Association to Melbourne, referred to in an article in our issue of October 8, was to the Warburton district, where the giant ferns and gum-trees, rising in some cases to a height of about three hundred feet, gave the visitors impressive views of Australian bush scenery. The two photographs here reproduced show the party watching a wood-chopping contest, and in one of the gullies of the forest rich in objects of botanical interest.]

NOTES.

THE Harveian oration on advances in knowledge regarding the circulation and attributes of the blood since Harvey's time, was delivered at the Royal College of Physicians on Monday, October 19, by Sir Douglas Powell. After the oration Sir Ronald Ross was presented with the Bissett Hawkins Memorial Medal for distinguished services in the advancement of sanitary science and public health.

THE question of the continuance of meetings of scientific societies during the war, raised by Dr. W. T. Calman in a letter which appears elsewhere in this issue, is one which each society must decide for itself after taking into consideration the papers likely to be forthcoming, and the number of fellows or members likely to attend meetings at which they are presented. It is to be hoped, however, that if meetings go on as hitherto, any German or Austrian members of the societies will absent themselves for the time being, as objection might be taken to their presence under existing conditions.

MANY leading men of science in the British Isles, as well as distinguished representatives of other branches of learning, have signed a statement which has just been issued in reply to manifestoes published by various university professors in Germany. The statement refers to the policy of national aggrandisement based on the threat of war advocated by von Treitschke, von Bülow, von Bernhardi, and strongly supported by public opinion in Germany; and it summarises the diplomatic papers in which the events are described that forced Great Britain into the present war if she wished to preserve an honourable position among nations. The concluding paragraph is as follows:—"The German professors appear to think that Germany has in this matter some considerable body of sympathisers in the universities of Great Britain. They are gravely mistaken. Never within our lifetime has this country been so united on any great political issue. We ourselves have a real and deep admiration for German scholarship and science. We have many ties with Germany, ties of comradeship, of respect, and of affection. We grieve profoundly that, under the baleful influence of a military system and its lawless dreams of conquest, she whom we once honoured now stands revealed as the common enemy of Europe and of all peoples which respect the Law of Nations. We must carry on the war on which we have entered. For us, as for Belgium, it is a war of defence, waged for liberty and peace."

THE Royal Photographic Society has just opened to the public a house exhibition of photographs by Mr. Lewis Balfour, "Bird Life on the Bass Rock." There are upwards of one hundred of these pictures showing the various sea birds and incidents in their lives. The public will be admitted free, daily from 11 a.m. to 5 p.m., until November 28.

THE second Thomas Hawksley lecture will be delivered in the meeting hall of the Institution of Mechanical Engineers on Friday evening, October 30, by Mr. W. B. Bryan, the subject being "Pumping and other Machinery for Waterworks and Drainage." The Thomas Hawksley fund was founded by Mr. Charles Hawksley to perpetuate the memory of his father who was president of the Institution of Civil Engineers in 1871 and 1872, and president of the Institution of Mechanical Engineers in 1876 and 1877. The income of the fund is devoted to the maintenance of a lecture and to the award by the council of the Institution of Mechanical Engineers annually a "Thomas Hawksley" gold medal, with or without a premium, in money, books, or otherwise for the best original paper read at a general meeting of the institution or printed in its proceedings.

PROF. DAVID TODD, who passed through London a few days ago on his return to the United States from Russia, where he observed the total solar eclipse of August 21, as will be described in a later issue, brought with him a very successful kinematograph film of the eclipse, and by the courtesy of Messrs. Pathé Frères it was projected upon the screen of their theatre in Charing Cross Road. The film reproduced the solar corona with the narrow crescents before and after it with great fidelity. It was taken by Dr. N. V. E. Nordenmark, of Stockholm, at Sollefteå, Sweden, latitude N. 63° 12′, longitude 45′ west of Stockholm, where the sky was absolutely free from cloud. The lens was a 50 mm. Zeiss of 305 mm. focus, and the exposures were about six to the second. In all there are more than seven hundred excellent pictures of the corona, which is well seen even into the partial phase.

The death of Dr. Anthony Traill, provost of Trinity College, Dublin (writes E. P. C.), removes a forceful personality from Irish life. Of striking all-round ability, never brilliant, but possessing an indefatigable power of work, he outdistanced many of his colleagues who, from the academic point of view, were more highly endowed. Taking his LL.D. at twenty-six, he obtained fellowship next year, 1865, and shortly afterwards he entered the medical school, taking his M.D. in 1874. In 1899 he was co-opted a senior fellow, and was appointed provost in 1904, *vice* Salmon. If he was wanting in some qualities usually looked for in a provost, he possessed, and in a high degree, others not so often found in academic men, and thus he was able to bring the college safely through the extraordinarily critical times of the Parliamentary settlement of the Irish University question, and the, in some ways more delicate one, of internal reform. For this reason, and the untiring energy with which he strove to widen its activities, he deserves the hearty gratitude of the college, and must be ranked as one of its most efficient provosts. Of the man himself, it is difficult to give an idea in a few lines. His interests were exceedingly wide. As an athlete, an alpine climber, a good cricketer, a rifle shot, as a college fellow and tutor, as a member of public boards and commissions, as a financial adviser to the Church of Ireland, he always acted up to the maxim, "Whatsoever thy hand findeth to do, do it with thy might." Up to his seventy-fourth year he was remarkable for bodily vigour, even then shooting over his bogs for an entire day without a sign of fatigue; and what must be regarded as his premature death at seventy-six was due to his almost contemptuous disregard of painful symptoms to which far younger men would have yielded. He was seen at his best as a most kindly and entertaining host in the family home at Ballylough.

Owing to the absorbing attention given by our newspaper Press to the war, we receive but the scantiest notices of important earthquakes, even when they occur in our own Colonies. From the *Morning Post* for October 15, we learn that, at 2.15 a.m. on the day before, an earthquake was felt all over the colony of Jamaica, strong enough to awaken the inhabitants, but not to cause any damage to buildings.

On October 17, at about 8 a.m., the whole of Greece was shaken by violent earthquake shocks, the first of which lasted twenty seconds. The centre was apparently near Thebes, where a number of houses fell, especially in the villages of Cappareni and Pirri, which were partially destroyed. Atalante and Chalcis were also seriously injured, and all the railway stations on the Larissa line were damaged. The shocks were also felt in the Peloponnesus, the Cyclades, Euboea, and the Ionian Islands. Several houses at Athens and the Piraeus were cracked, but none of the ancient monuments suffered. A few persons were injured, but, so far as known, no lives were lost. Though much less severe than the earthquakes of April 20 and 27, 1894, the recent shock seems to have originated in the same region, and probably in the same great fault. This fault was traced by M. Papavasiliou for a distance of thirty-three miles, passing through Atalante, in a direction parallel to the adjacent Gulf of Euboea. The throw was generally small, though in places it amounted to as much as 4 or 5 ft. (see Nature, vol. l., p. 607).

The *Philippine Journal of Science* for April last supplies an interesting account by Mr. E. B. Christie of the pottery industry at San Nicolas, in the Ilocos Norte province. A modified form of the potter's wheel is used, the clay being shaped into a short, thick cylinder, and laid on a board which rests upon a second board, but not connected with it by a bearing-pin. From time to time the woman worker gives the upper board a turn with one hand while she works the clay with the other. At first she uses only her fingers to shape the vessel. Later on she holds a smooth stone against the inner surface of the vessel with her left hand while with the other she works a paddle to form the outer surface. With the paddle she beats the clay, causing it to spread. When the vessel is complete, she smooths the outside with a shell and smears it with red earth mixed with water in order to produce a uniform colour. If she does not do this, the clay assumes a weak, irregular colour when it is fired. If she desires to blacken the pot, it is, while still very hot, covered with rice bran. This becomes imperfectly consumed, and leaves a black deposit on the clay. The industry is purely domestic, but it is of some economical importance.

In the October number of *Man* Dr. H. Basedow furnishes an obituary notice of Mary Seymour, the last relic of the lost Tasmanian race. Born in 1833, she died in 1913, her mother being a full-blooded Tasmanian aboriginal, who married a whaler named Nat Thomas. On her marriage to Joseph Seymour, Mary for the first time learned a little English, and she claimed to be the first woman born on Kangaroo Island. She used to give graphic accounts of her experiences in the pioneering days of South Australia. She was of short but robust stature, and her features indicated a keen intellect combined with a determined will. Seen in profile, the deep notch below the glabella at the root of the nasal bones betrayed a Tasmanoid inheritance, described by Dr. Garson (Journal Anthropological Institute, vol. xxvii., plate 27) as one of the characteristics of the race. The hair was silken, white, and wavy, the eyebrows bushy. Her lips and skin were remarkably free from hair, and her skin was of a dark bronze-brown and wrinkled with age. The lower jaw was well developed, and had a big loose flap of skin attached to it that produced a very noticeable double-chin. The keen, small eyes lay deep within their sockets; their colour was a greyish-brown. It is interesting to compare the photographs accompanying the article with those published by Mr. H. Ling Roth in his classical memoir descriptive of this interesting race.

The preventive treatment of fowl cholera is dealt with by Mr. Philip B. Hadley in Bulletin 159, Agricultural Experiment Station of the Rhode Island State College, U.S.A. Various avirulent cultures of the

fowl cholera micro-organism were found to be protective to rabbits against certain virulent strains of the organism, either singly or in combination. Attempts are now being made to produce a corresponding protection among poultry, for fowl cholera is a disease which frequently causes considerable loss to the poultry farmer.

In the report of the Leyden Museum of Natural History for the year ending September 1, 1914, Dr. E. D. Van Oort, the director, pays a well-deserved tribute to the work of his predecessor, the late Dr. Jentink. The additions to the collection were numerous, and the number of visitors during the year 3134.

Recruits of the Transport Corps are receiving instruction from their officers in the north hall of the British Museum (Natural History) on the external characters and osteology of the horse. For this purpose a mounted skin and a skeleton of the horse have been removed from their cases and placed on the floor of the hall, from which the general public are excluded during the periods of instruction. We understand that the officers of the Veterinary Department, aided by the Transport Corps, have succeeded in rendering a large number of wounded or otherwise injured horses at the front fit for further service; such horses include many taken from the Germans.

In an editorial article on eugenics and war in the October issue of the *Eugenics Review*, it is pointed out that "the British Empire, by reason of maintaining her army on a voluntary basis, must inevitably suffer racially more than other nations. The battle death-rate must strike her unevenly and reduce the number of her males amongst the class from whom it is most desirable that she should produce the stock of the future. In the countries with universal compulsory service, the reduction in effective males will be spread over the entire population; good and bad will alike be reduced. In this country the types which are physically and mentally superior will volunteer for active service. . . . The sample of those killed will not be the average of the race, but the best type of the race. . . . Although the system may give victory and national prestige, the racial effect must be injurious."

The contents of Nos. 3 and 4 (issued in a single cover) of vol. xxxvi. of *Notes from the Leyden Museum* consist exclusively of papers on invertebrates, the longest of which is a continuation of Dr. R. Van Eecke's "Fauna Simalurensis," dealing with Indo-Australian Lepidoptera. Dr. J. H. Vernhout also contributes a further instalment of the results of his study of the land and fresh-water molluscs of the Dutch American colonies, discussing in this instance those of Curaçao. It would be natural to expect that the land-snails of the Curaçao group of islands should exhibit a close affinity with those of Venezuela; as a matter of fact, this is far from being the case, only seven out of twenty-five species recorded from the three islands being common to the mainland. Nor is this all, for many even of the genera are quite unknown on the South American continent, but are more nearly related to or identical with Central American and Jamaican types.

In these columns (October 2, 1913) reference was made to the regional survey undertaken by the Croydon Natural History and Scientific Society. In the 1913–14 volume of the society's Proceedings and Transactions, which we have received, an account of the general progress of this survey is given in the form of a report by the survey committee. The scheme has aroused much interest, both within and outside the society, has caused the revival of the photographic section, and increased activity in the botanical, zoological, and archæological sections, and has brought about closer co-operation between all the sections of the society. Mr. C. C. Fagg, secretary of the regional survey committee, contributes an introductory paper on the mineral and agricultural industries of the survey area, dealing with these from the geographical point of view, with plates and a geological (drift) map of the Croydon area.

We have received the report of the Botanical Survey of India for the year 1913–14, in which the officiating director of the survey, Mr. C. C. Calder, summarises the extensive and valuable work done during this period. Under the heading of systematic work, references are made to the results, published in the records of the survey and in other journals, of the field investigations made by members of the survey staff and others, and it is interesting to note that in many cases these results include not only lists of species collected, but studies of the vegetation in various aspects, the distribution of the species being correlated with the adaptations of the plants to their environment and their aggregation into plant communities. This ecological side of field work in botany has not hitherto figured largely in Indian botanical publications, but as the systematic survey proceeds it will doubtless be accompanied by further and more intensive distributional and ecological study. The chemical part of the work hitherto undertaken at the Indian Museum, Calcutta, has now been transferred to other departments, while the newly appointed economic botanist to the survey, Dr. H. G. Carter, has begun the collection of materials necessary for the compilation of the work on Indian plants of economic importance urged by the Royal Society some years ago. There is also in active preparation an index to all species of Indian plants not included in Hooker's "Flora of India"; this index already contains nearly 900 species, and will be published as a single number of the records of the survey.

The report for the past year of the New Zealand Department of Scenery Preservation states that 3000 acres were reserved, bringing the total area of scenic reserves in the Dominion to 214,000 acres, comprised in 363 different reserves. It is pointed out that the great bulk of this land is unsuitable for settlement, while it assists to conserve water, protect soil, and prevent denudation. Private residents have shown remarkable munificence in presenting areas to the

Government. The Scenery Preservation Act of 1903, consolidated in the Act of 1908, provided a total sum of 100,000*l*. Each year a portion of this is authorised for expenditure; a balance now remains of 27,136*l*. It is curious that the native Maoris are the only section of the population that does not approve of the movement. Among details of interest the following may be cited. Deer are extremely detrimental to forest. The lakes of New Zealand have been formed by the erosive action of huge bodies of ice or by volcanic action; but Waikaremoana was formed by an immense fault in the stratification of the country. The greater part of forest is beech, with its two varieties of black and red (*Nothofagus solanderi* and *fusca*). Native flowers and birds are well looked after in these reserves, and the National Society for the Protection and Preservation of New Zealand Forests and Bird Life has just been formed. "Each member of the society should consider himself an unofficial ranger." It is noteworthy that most of these reserves coincide with health resorts and sporting centres. Perhaps the most beautiful of them all is Day's Bay, only forty minutes from Wellington, and a favourite excursion. This bit of forest is as it was 1000 years ago. Another gem is the reserve on the Waganui river, which is "the finest sight of its kind in the whole world." "It is no compliment," said a Russian traveller who had seen the great rivers of the world, "to call the Wanganui 'the New Zealand Rhine.'"

IN Publication No. 4 of the Meteorological Institute of Chile Dr. W. Knoche gives a very interesting discussion of the hourly observations specially made at Mataveri, Easter Island, for one year ended April, 1912. From a meteorological point of view the position of the island is important for the study of atmospherical circulation; it lies in the south-east Pacific Ocean (approximately 27° 10′ S., 109° 26′ W.) in one of the permanent areas of high barometric pressure, and within the limit of the trade-winds, especially in summer. Notwithstanding the uniformity of the climate, one year is naturally too short a period to deal with satisfactorily, and we are glad to see that Dr. Knoche has been able to make arrangements for observations to be continued, although on a smaller scale. The mean barometric pressure (M.S.L.) was: January, 30·08 in., July, 30·06 in., year, 30·06 in.; but conditions are said to differ considerably in different years, probably owing to the shifting of large masses of air in the high-pressure area. Rainfall during the summer half-year amounted to 22·2 in., and in other months to 27·9 in. The mean of the hottest month was 74·8° in February, and of the coldest 64·2° in October. The absolute extremes were 87·8° in February, and 51·1° in July. An unpleasant feature of the island is that it is infested by large swarms of mosquitoes. The volume is well illustrated by curves and diagrams.

THE Journal of the Washington Academy of Sciences for September 19 contains a short account of the results obtained by Messrs. G. K. Burgess and J. N. Kellberg, of the Bureau of Standards, during an accurate investigation of the changes of the electrical resistance of pure iron wire up to a temperature of 1000° C. A platinum and an iron wire of about an ohm resistance were wound on porcelain insulators in an evacuated quartz tube, heated in an electric furnace. The resistance of each wire was determined by the bridge method with an accuracy of 0·00001 ohm, during the slow heating and cooling of the furnace. That of the platinum wire served to determine the temperature of the iron wire. The resistance of pure iron on heating was found to increase at a rate which itself increases up to 757° C., the temperature at which the iron ceases to be ferromagnetic. Above that temperature the rate of increase again decreases, so that at 895° C. the resistance reaches a maximum, and at 906° C. a minimum beyond which it appears to increase regularly. On cooling the minimum occurs at 880° C., the maximum at 870° C., and the change in the rate of decrease again at 757° C. The authors attribute the non-reversible change at the higher temperatures to recrystallisation, but they have not been able to detect any crystalline change at the 757° C. point.

THE forthcoming books of the *Cambridge University Press* include:—A Theory of Time and Space, by A. A. Robb; The Surface of the Earth: Elementary, Physical, and Economic Geography, by H. Pickles; The House-Fly, by Dr. C. Gordon Hewitt (in the Cambridge Zoological Series); A Book of Simple Gardening, by D. Lowe; and (for the University of Chicago Press) Water Reptiles of the Past and Present, by S. W. Williston; and Assyrian and Babylonian Letters, edited by R. F. Harper, vol. xiv.; and *Mr. John Murray* announces:—A Hunter-Naturalist in the Brazilian Wilderness, by Theodore Roosevelt, illustrated; Emma Darwin: a Century of Family Letters, 1792–1896, edited by H. Litchfield, two vols., illustrated (the second volume of the work will contain many unpublished letters of Charles Darwin, supplementing his biography by giving some idea of the more intimate side of his life); Concerning Animals and other Matters, by E. H. Aitken ("EHA"), with a Memoir of the author by Surgeon-General W. B. Bannerman, illustrated; A History of the Gold Coast and Ashanti, from the Earliest Times to the Beginning of the Twentieth Century, by W. W. Claridge, two vols.; a new and enlarged edition of The Rudiments of Practical Mathematics, by A. Consterdine and A. Barnes.

MANY rare and valuable books and papers relating to mathematical, physical, and natural sciences, and to technology, are included in a catalogue, "Bibliotheca Chemico-Mathematica," part x., just received from Messrs. Henry Sotheran and Co., 140 Strand, W.C., and 43 Piccadilly, W. The catalogue contains descriptive notes upon a large number of the books and authors, and should be of assistance to bibliophiles in search of important scientific works. We notice particularly books by, and on, Pasteur, Paracelsus, Priestley, Réaumur, Regiomontanus, Respighi, and many other authors, both ancient and modern.

OUR ASTRONOMICAL COLUMN.

COMET 1913*f* (DELAVAN).—Delavan's comet is now a more prominent object in the evening sky, and can be picked up by anybody without an ephemeris: it has a tail of considerable length and brightness. The comet is rapidly moving in declination covering about 3° in four days. It is also visible as a morning object. The comet passes perihelion on October 26, and in the meantime should become brighter. The following is a continuation of Prof. Biesbroeck's ephemeris up to the end of the present month:—

	R.A. h. m. s.		Dec. ° ′
Oct. 22 ...	13 56 0	...	+29 33
26 ...	14 12 0	...	26 27
30 ...	14 26 36	...	23 25

We are indebted to Prof. David Todd for a print, here reproduced, of a photograph of the comet taken

Delavan's Comet, September, 1914. Photographed at Stockholm Observatory. Exposure, one hour.

last month by Dr. Karl Bohlin at the Stockholm Observatory.

ENCKE'S COMET.—The October number of the *Observatory* publishes the elements and ephemeris of Encke's comet as computed by M. L. Matkewitsch, of Pulkova. The latter for the present month are as follows:—

	R.A. h. m. s.		Dec. ° ′
Oct. 20 ...	8 29 44	...	+61 37
22 ...	9 26 3	...	60 28
24 ...	10 20 21	...	57 42
26 ...	11 7 51	...	53 27
28 ...	11 46 43	...	48 7
30 ...	12 17 33	...	+42 10

The corrections to this ephemeris on about October 27 are given as R.A. +8s., declination −6′. It is stated that the comet will be nearest the earth on October 27, and is generally a fairly conspicuous object when perihelion occurs in winter. It has sometimes been glimpsed with the naked eye.

THE RECENT ECLIPSE EXPEDITIONS.—Further news is to hand regarding the experiences of some of the recent eclipse expeditions (the *Observatory*, October). The party from the Solar Physics Observatory, Cambridge, seems to have had particularly bad luck, for not only did a thick detached cloud completely hide the whole of the total phase, but even the telegrams announcing the complete failure of the observations never reached home. Prof. Newall, who writes this account, draws the moral of "the importance of spreading the camps of observing parties even in the restricted area chosen for a station of observation." Prof. Perrine set up his instruments in the same camp as the Cambridge party, and suffered a similar fate. While this camp was about four kilometres from Theodosia, on a site one kilometre nearer Theodosia, MM. Beljawsky and Neujmin obtained observations for about 30 seconds. At Theodosia the eclipse was seen in blue sky between patches of cloud, and observations were made during the whole total phase. Among the observers there were Signor Ricco, Count de la Pluvinel, Dr. Donitch, Prof. Sternberg (Moscow), M. Crétien (Nice), and M. Ascarza (Madrid). Dr. Backlund's expedition to Riga met with success, and Prof. Newall refers to "the beautiful photographs of the corona" secured by M. Kostinsky, who was of that party. Prof. Campbell and his party, who observed at Kiev, had adverse weather conditions.

An interesting account of the Greenwich Eclipse Expedition is given by Mr. H. S. Jones, one of the official observers. This party, at Minsk (Russia), had a narrow escape, for "when totality commenced a long cloud was approaching the sun, but fortunately did not reach it until the last second of totality." The whole programme was thus carried out. The corona he describes as "comparatively bright, and of a steely-blue whiteness, with no trace of yellow—it was of the intermediate type, with four streamers, resembling somewhat the 1898 corona."

SOCIETÀ DEGLI SPETTROSCOPISTI ITALIANI.—The July and August numbers of the *Memorie della Società degli Spettroscopisti Italiani* contain numerous contributions of interest on various subjects. In the July number the variable R. Leporis is dealt with by E. Padova, who publishes some new observations and a calculation of the period, which he gives as 438·93 days. This is Hind's famous crimson star, which in 1845 was described by him as "of the most intense crimson, resembling a blood-drop on the background of the sky. . . ." Some new observations and a discussion of them relating to the variable ST Ursæ Majoris are communicated by G. Silva. A preliminary note by E. Paci describes the observations made for the determination of the latitude of the centre of the cupola of the Etna Observatory. The observations were secured during 1913 by the Horrebow-Talcott method, and the value derived was +37° 44′ 8·392″. The last-mentioned author contributes two papers to the August issue, the first dealing with a study of the Ertel meridian circle of the Catania Observatory, and the second with the difference of longitude between Catania and Palermo as determined by telegraph by Ricco and Zona in 1894. After giving the details of the observations, he derives the value 6m. 54·7826s. ± 0·0055, as being the difference of longitude between the two observatories. This number concludes with the obituary notices and portraits of Giuseppe Lorenzoni and Edward S. Holden, written by A. Antoniazzi and W. W. Campbell respectively.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THE Australian meeting of 1914 will always occupy a prominent place in the annals of the British Association, if only on account of the interest attaching to the proceedings of its Anthropological Section. Not only did the representatives of this rapidly developing branch of science muster in full strength, but their

discussions, bearing as they did largely on Australian problems which are concerned with the most primitive of existing human types, were throughout directed to fundamentals. Needless to say, the shadow of the great war raging in Europe cast a chill over the spirits of all concerned, and it needed a certain moral effort to carry through a programme in which, at least as originally designed, business and pleasure claimed equal shares. As it was, the inclination of the balance towards the side of seriousness was not without its advantage for those students who found the allotted time all too short to enable them to cope with Australia's magnificent ethnological collections. These must be seen before one is in a position to assign to Australian culture its true place in the evolutionary scale.

In Western Australia certain anthropologists of the advance party got into touch with aboriginals, and again in South Australia Prof. Stirling organised a most successful expedition of the whole section to Milang, where a large group of the Narrinyeri tribe were on view, so that everyone was presently hard at work, spurred on by the discovery that, even if degeneration has gone far, there still exists plenty of valuable lore to be garnered. It must be added that in the Adelaide Museum Prof. Stirling has amassed wealth untold in the way of ethnological material, special value attaching to the spoils from the central deserts, illustrative as they are of the life of the now famous Arunta and their congeners. At Adelaide, too, Prof. Sollas gave an evening lecture on prehistoric man, which delighted his large audience.

Formal proceedings opened at Melbourne on Friday, August 14, Prof. G. Elliot Smith leading off with a remarkable comparison of certain customs and inventions of the ancient Egyptians with those of primitive peoples of the Far East, the full development of his argument being unfortunately somewhat hampered by want of time. After Dr. A. Low had described the finding of certain curious cists of the Bronze age in the north-east of Scotland, the section adjourned to the museum. Here, first of all, Messrs. A. S. Kenyon and D. J. Mahony exhibited and explained a very rich series of aboriginal stone implements, extending from the well-polished adze at one end of the scale to the roughest Palæolithic and even Eolithic types at the other. Then Prof. Baldwin Spencer showed all manner of specimens of native handiwork, including a remarkable series of drawings on bark from the Alligator River, Northern Territory.

On Tuesday, August 18, Mr. Balfour gave forth the results of his investigations into the remains of an early Stone age in South Africa. He was followed by Dr. Marett, who, as chairman of the committee that has undertaken the recent excavation of a Mousterian cave habitation in Jersey, was able to report a rich harvest of discoveries. Prof. G. Elliot Smith and Prof. J. Symington then engaged in a discussion, scarcely less impassioned than it was profound, concerning the possibility of deducing the shape of the human brain from that of the inner surface of the cranial wall, with special reference to the primitive characters that have been attributed on these grounds to the Piltdown skull. Major A. J. N. Tremearne, who was returning next day to Europe on military duty, wound up the morning with a well-illustrated account of the Bori, or disease-spirit, ceremonies of certain Hausa colonies in North Africa. In the afternoon Prof. Felix von Luschan, of Berlin, delighted a large audience with a discourse dealing with the question, "Are we degenerate?" and embodying various more or less startling proposals of a practical nature in the interest of eugenics.

On Wednesday, August 19, the whole morning was devoted to a debate, initiated by Dr. Rivers, on the subject, "Is Australian Culture Simple or Complex?" The section listened with the greatest interest to Dr. Graebner, who holds strong views on this particular topic, and the ball was kept rolling by Prof. Sollas, Prof. Berry, Prof. von Luschan, Prof. Haddon, Rev. J. Mathew, Mr. Balfour, Mr. A. R. Brown, Dr. Malinowski, Dr. Marett, and others. The discussion as a whole was most profitable, though perhaps it raised more problems than it solved. It remains to add, in reference to proceedings in Victoria, that, besides enjoying unlimited facilities for study at the museum, and in Prof. Berry's well-equipped department of anatomy, the anthropologists had the opportunity of visiting an aboriginal quarry at Fisherman's Bend, near Melbourne, and, again, of making further acquaintance with aboriginals, since the Colanderrk station near Healesville provides types from several parts of the continent, the older members of the native community preserving considerable traces of their former culture, as witness their corrobborree songs which Prof. von Luschan was careful to record by means of the phonograph.

Arrived at Sydney, the section on Friday, August 21, was treated by Sir Everard im Thurn to a presidential address which summed up in telling fashion his impressions of the character of the so-called "savage" in the shape of the primitive Fijian. He emphasised "the enormous, scarcely conceivable difference in habit of thought which separates the savage from the civilised man," and showed on the strength of his experience as an administrator that the process of mutual adjustment, so far as it is possible at all, must necessarily be slow, demanding, too, on our part much patience, good will, and anthropological science. Dr. Ashby followed with an account of various archæological discoveries of his own at Malta. Then a most sensational announcement was "sprung" on the meeting. It appears that, just about the time that the pioneers of the British Association were setting foot on Australian soil, a highly petrified skull was found on the Darling Downs, Queensland, such as may very well prove to be assignable to Pleistocene times, Pleistocene man in Australia having hitherto existed only in the sphere of pure hypothesis. Profs. David and Wilson, who exhibited the specimen to the much-moved section, were careful to state the case for the attribution of a high antiquity to the specimen with the greatest caution, the chief argument, pending a full study of the anatomical characters, resting on the fact that the state of petrification which the skull displays corresponds closely to that observable in regard to the remains of Diprotodon and other extinct animals from the same district. The Rev. Dr George Brown then read extracts from an interesting paper on Samoan folk-lore, which he has offered to *Folk-Lore* for publication.

On Tuesday, August 25, the morning session opened with a discussion, led by Dr. Haddon, on the importance of the study of anthropology for the administrator. The president lent the weight of his great authority to the plea for a more thorough instruction of those who are set over natives in the mental habits and culture of their charges, and something was said by other speakers of what is being done by some of the British universities to provide an education in anthropology, both theoretical and applied. Dr. Rivers next spoke of gerontocracy in its bearing on marriage in Australia, showing how the old men's tendency to appropriate all available wives has in certain cases left its mark on the permanent structure of society. Mr. A. R. Brown followed with an account of the varieties of totemism in Australia, his classification covering several new types recently discovered by himself in Northern Territory, or by Mrs. Bates in the Eucla district. In the afternoon the section repaired to the

museum, where local experts provided a full programme. Mr. R. Etheridge commented on various ethnological exhibits from Australia and New Guinea, being part of the rich collection over which he presides. Mr. S. A. Smith dealt with various anatomical peculiarities of the Australian aborigines. Messrs. Flashman, Hedley, Enright, and Elmore were also to thank for interesting contributions and exhibits, while a great debt is due to Prof. J. T. Wilson, who, despite the severe duties of military censor, managed to arrange for so strongly supported and well-organised a sectional meeting as that of the anthropologists at Sydney.

It has proved quite impossible to do justice here to the multitudinous experiences which, altogether apart from the formal proceedings of the section, have served to make the Australian visit of the association, and of the anthropologists in particular, at once pleasant and profitable in a quite unique way. The unfailing kindness and hospitality shown by our overseas brethren one and all make it a too invidious task to assign special thanks, and it must suffice, by way of showing due gratitude, to see to it that, in the way of science, Australia's myriad wonders and excellences are henceforth rated at their proper worth. As for the anthropologists in particular, they cannot be accused of having neglected Australia, since it has ever been the happy hunting-ground of the theorist seeking to reconstitute the life of primitive man; but at any rate it is likely that henceforth the study of Australian problems will proceed more intensively, inasmuch as the astonishing wealth of the Australian museums has been realised from near at hand. Moreover, we come away feeling that we have left on the spot plenty of men capable of carrying out the best kind of anthropological work, if only those in control of ways and means can be induced to make proper provision for a branch of study in which Australia might well aspire to lead the world.

THE IRON AND STEEL INSTITUTE.

ONE of the most noteworthy of the papers which was to have been presented at the Paris meeting, abandoned on account of the war, describes a new method of heating blast-furnace stoves. It appears from experiments on a stove carried out at the Neunkirchen works of Messrs. Stumm Brothers that, in their ordinary practice, of the total heat put into the stove about 26 per cent. was carried away in the waste gases and 18 per cent. was lost by radiation. Accordingly the efficiency of the stove was not more than 56 per cent.

As the author, Dr. Spannagel, points out, it is almost the universal practice to heat the stove for three to five hours and then send the blast through for one to one and a half hours. Messrs. Pfoser and Strack set themselves the task of finding out why the chequer work gives up its heat to the blast in a so much shorter time than is required to collect the heat from the waste gases, and they found that it was due to the fact that the velocity of the gases is different in the two cases. Under present conditions, when the temperature of the stoves is required to be raised the velocity of the gas is increased, and this causes the temperature of the waste gas to rise. Hence the waste gas losses are increased and the efficiency is reduced. The experimenters found, however, that this rule only holds up to a certain point, and that if the velocity is increased still further the temperature of the waste gas not only ceases to rise but begins to fall. The reason for this is probably that with a low velocity gas the molecules flow almost parallel to each other and the friction with the bricks is inconsiderable and consequently it is only the molecules which flow close to the chequer brick which transmit their heat by direct contact, whereas the remainder impart their heat slowly by radiation. If now the velocity is increased to the usual extent, the friction of the gas molecules against the brick causes some eddying in the outer layer of gas, and the inner particles are partly drawn into movement. The heat transmission is more rapid, but since the gas velocity is greater more heat is carried off unused. By raising the velocities still more the friction between the gas molecules and the brick becomes so great that the particles rebound and impart their rapid movement to those even in the centre of the current. Accordingly, the violent eddying produced brings all the molecules rapidly in contact with the chequer brick, and they give up their heat rapidly. Hence the temperature of the waste gas falls. The principle of the method, therefore, is precisely the same as that of the high-speed boiler designed by the late Prof. Nicholson, and indeed the authors say, "Experiments which have already been made in boiler firing have given particularly favourable results."

In heating the stoves the velocity of the gas is brought up to the necessary point by blowing in compressed air at a pressure of about 16 in. of water. At the first trial the heating period was reduced to $1\frac{1}{2}$ hours, "the temperatures of the waste gases and of the blast being 350° C. maximum, and 800° C. respectively, as compared with the former heating period of $4\frac{1}{2}$ to 5 hours, and a waste gas temperature of about 700° C. maximum, the blast temperature being the same." The experimenters have found it advantageous to use highly cleaned gas, since it enables the cross section of the heating passages to be reduced and the surface of the chequer brick to be substantially increased.

One of the outstanding problems, both of the iron-maker and the steel-maker, has always been the utilisation of the heat contained in slags. It is not so many years ago that the slags themselves were wasted. At the present day the uses of the various types of slags are many and various, but hitherto their sensible heat has been unutilised. Accordingly, the paper by Mr. W. L. Johnson, of Messrs. Bell Brothers, on this enormously important industrial problem, recording as it does the results of tests that have been in progress for four years, is well worth studying. The principle of the method has been to generate steam by allowing the molten slag to flow into a suitable generator and to utilise it in an exhaust steam turbine. In the first tests the steam was utilised direct from the generator, but these were abandoned in favour of an indirect method in which a water heater and a heat exchanger were introduced between the primary generator and the turbine. The calandria used was a "Kestner single-effect climbing film evaporator," and consists of two parts, the calandria proper and the separator. A certain amount of sulphur was deposited, but there seems to have been very little corrosion of the tubes of the heater. A vacuum of about 9 in. of mercury was maintained in the separator so that the water boiled at 90–91° C. "With steam from the slag at 100° C. and keeping a temperature in the calandria of 91°, the mean of twenty-two experiments gave 173 gallons of water evaporated per hour, and the average steam per hour condensed in the calandria and heater was 190·2 gallons. The feed water entered the heater at an average temperature of 24·6° C., and entered the calandria at an average temperature of 89°, *i.e.* 91 lb. of clean water was evaporated for every 100 lb. of steam from the slag." The amount of available steam from the slag was determined by condensing and measuring it. Seven experiments gave as a mean 1017 lb. per ton of slag. Deducting 6·6 per cent. for escape with the incondensable gases, 950 lb.

remain, and 90 per cent. of this gives 855 lb. of clean steam available for the turbine. "Since modern exhaust steam turbines with a full load and a vacuum of 28½ in. can be guaranteed under the above conditions to use not more than about 27 lb. per horse-power, this gives 31·6 horse-power per hour per ton of slag per hour."

In his paper on the use of liquid ferro-manganese in the steel processes, Mr. Axel Sahlin points out most of the methods of adding ferro-manganese are wasteful both from the point of view of heat efficiency and the percentage of manganese oxidised. He describes a new type of arc furnace invented by Mr. Ivar Rennerfelt, which he claims has been successfully used for this purpose. This furnace is fitted with three electrodes so placed that, when the current is turned on, the arcs, instead of passing directly between the points of the electrodes are deflected downwards, forming an inverted arrow-head or "fleur-de-lys" with a height of 6 to 12 in. Adjustment is made so that the point of the "arrow-head" impinges on the surface of the metal. Manganese smoke was noticed for a few minutes after charging, but then ceased to be evolved. The tests which have been carried out indicate that for the melting of one ton of 79 per cent. ferro-manganese, charged into an empty and pre-heated furnace, about 450 units are required. This corresponds to a furnace efficiency of 78–79 per cent., and is very much better than anything that has been achieved with other types of electric furnace. Moreover, analyses showed that there was not only no loss of manganese and iron in the melting process, but even a gain of 0·6 per cent. in each case.

The industrial production of electrolytic iron now appears to be entering the "practical" stage. An account is given by Prof. Guillet of the manufacture of such iron in the form of tubes of considerable size. The direct production of sheets is also contemplated. The iron is deposited on a revolving kathode from a neutral solution of iron salts (the composition of which is not given), the electrolyte being maintained neutral by the circulation of the liquid over the surface of the iron. From time to time the liquid receives additions of iron oxide with the object of reducing the deposition of hydrogen on the kathode. In this way currents of 1000 amperes per square metre have been successfully employed, and an iron of excellent quality is said to have been obtained. Analyses show that it is very low in the usual impurities even when prepared from very impure pig-iron. When freshly prepared it is hard and brittle, partly on account of the fact that it has been deposited in a condition of strain and partly because it contains hydrogen. The former aspect is well seen in the photomicrographs, which reveal a typical martensitic structure, and it is interesting to observe that the normal polygonal structure of a pure metal is not obtained until the annealing has been carried to 800°–900° C. Photographs of the crushing tests of tubes indicate a very remarkable degree of plasticity. The direct production of sheets without rolling would certainly be an important technical achievement and such material on account of its high degree of purity would have important applications in electrical machinery.

H. C. H. CARPENTER.

PAPERS ON HEREDITY.

STUDENTS of heredity have followed with the greatest interest Dr. L. Doncaster's experimental and cytological work with the Magpie Moth (*Abraxas grossulariata*). In the last number of the *Journal of Genetics* (vol. iv, 1914, pp. 1–21, plates i–iii) he brings forward further interesting results on the relations between chromosomes, sex-limited transmission, and sex-determination in that insect. He confirms the observation that in a strain of Abraxas, which in each generation produces families consisting entirely of females, the oogonia have only fifty-five chromosomes instead of the fifty-six normal to the species. It is thus established that the females are here heterozygous as regards sex-character, whereas in many insects the males are known to be heterozygous. Dr. Doncaster found that one female of this remarkable strain carried fifty-six chromosomes, while other females of the same brood had clearly fifty-five. "In the same brood there was failure of sex-limited inheritance of the *grossulariata* character [as contrasted with the factor producing the variety *lacticolor*] in two cases, in such a way that the *grossulariata* mother transmitted this character to two of her daughters (out of a total of sixteen) instead of, as normally happens, only to her sons. It is suggested that this may be correlated with the extra chromosome found in one female of this family, the *grossulariata*-bearing chromosome having become separated abnormally from the sex-chromosome."

Another noteworthy recent paper on the problems of inheritance is Dr. Leon J. Cole's account of the relations of the principal colours in Pigeons (*Rhode Island State College*, Bulletin 158). He concludes that there are four principal factors concerned—two for the pigments black and red, an intensity and an extension factor. The absence of the intensity factor makes black dun and red yellow, while the absence of the extension factor produces blueness. "Reversion to the wild blue Rock Pigeon type in domesticated pigeons is due simply to a recurrence of the particular combination of factors which are present in *C. livia*." White plumage is explained by the presence of an unknown number of pigment-inhibiting factors which are supposed to check the appearance of colour on different regions of the body.

THE PLACE OF WISDOM (SCIENCE) IN THE STATE AND IN EDUCATION.[1]

"So soon as men get to discuss the importance of a thing, they do infallibly set about arranging it, facilitating it, forwarding it, and rest not till in some approximate degree they have accomplished it."—CARLYLE.

THIS, doubtless, is a true statement; the difficulty is, however, to persuade men of the importance of a thing. We come to persuade you. As an association we are now eighty-four years old: our main purpose has been to obtain a more general attention to the objects of science and a removal of any disadvantages of a public kind which impede its progress—let me also add, its application to culture and to the public service.

By holding meetings, year after year, in the principal towns of the British Isles, the association has at least brought under notice the fact that science is a reality, in so far as this can be testified to by several hundreds of its votaries meeting together each year to consider seriously and discuss the progress of the various departments. On the whole, dilettanti have had little share in our debates. The association has already carried the flag of knowledge outside our islands, thrice to Canada and once to South Africa; now, at last, we make this great pilgrimage to your Australian shores; still we are at home. What message do we bring with us?

In 1847, when this city was but an insignificant town, it was visited by an Englishman who afterwards became eminent not only in science but also

[1] From an address to the Educational Science Section of the British Association at Melbourne, August 14, by Prof. Henry E. Armstrong, F.R.S.

as a literary man—Thomas Henry Huxley; he was then surgeon on board the surveying ship *Rattlesnake.* In 1848 Huxley visited Sydney, and there met the gracious lady, only recently deceased, who became his wife. In after years he achieved a great reputation on account of his services to education.

Lecturing in London in 1854, he defined science as "trained and organised common sense"—a definition often quoted since; none could be more apposite, though it must be remembered that "common sense," after all, is but an uncommon sense.

A few years later, in a public lecture at South Kensington, Huxley spoke to the following effect:—

"The whole of modern thought is steeped in science; it has made its way into the works of our best poets and even the mere man of letters, who affects to ignore and despise science, is unconsciously impregnated with her spirit and indebted for his best products to her methods. I believe that the greatest intellectual revolution mankind has yet seen is now slowly taking place by her agency. She is teaching the world that the ultimate court of appeal is observation and experiment and not authority; she is teaching it the value of evidence; she is creating a firm and living faith in the existence of immutable moral and physical laws perfect obedience to which is the highest possible aim of an intelligent being.

"But of all this your old stereotyped system of education takes no note. Physical science, its methods, its problems and its difficulties, will meet the poorest boy at every turn, and yet we educate him in such a manner that he shall enter the world as ignorant of the existence of the methods and facts of science as the day he was born. The modern world is full of artillery: and we turn our children out to do battle in it equipped with the shield and sword of an ancient gladiator.

"*Posterity will cry shame on us if we do not remedy this deplorable state of things. Nay, if we live twenty years longer, our own consciences will cry shame on us.*"

These words were uttered in 1861. Now, after more than fifty years, not twenty merely, we still go naked and unashamed of our ignorance: seemingly, there is no conscience within us to cry shame on us. I have no hesitation in saying that, at home, at all events, whatever your state here may be, we have done but little through education to remedy the condition of public ignorance which Huxley deplored. In point of fact, he altogether underrated the power of the forces of ignorance and indifference; he failed to foresee that these were likely to grow rather than to fall into abeyance. In England, what I will venture to term the Oxford spirit still reigns supreme—the spirit of the literary class—the medieval spirit of obscurantism, which favours a backward rather than a forward outlook.

Wherein was Huxley out in his forecast? In 1861 the claim of science was already strong, but think what has been done since that time—what we can now assert of its conquests! In the interval, even within my recollection, the whole of our ironclad fleet has been created, rifled cannon, smokeless powder and dynamite have been introduced, and this last, in combination with the discovery of the causes of yellow fever and malaria, has made the Panama Canal possible, an entirely revolutionary work of man's interfering hands. The *Great Eastern*, which could not be launched at first on account of her size—as a lad, I saw her sticking in the stocks—was always a failure, because she was outside the fashion of her time, yet has given rise to a host of ocean leviathians of far larger size; the steam-turbine has entered into rivalry with the reciprocating steam-engine; cold storage has revolutionised ocean transport, so that fresh food can be carried from this continent to remote England and Europe. Electricity, then a puling infant, is grown to giant size; not only have we deep-sea telegraphy and mechanical speech in the form of the phonograph and telephone, but wireless communication, the electric light, electric transmission of power, electric traction—even the waterfalls of the world are tamed through the turbine and made subservient to our will for motive purposes or in the production of temperatures bordering on those of solar heat, by means of which, too, we can draw food for plants, at will, from our atmosphere by combining its constituents into the form of a fertiliser. The use of oil-fuel in the internal-combustion engine has been made possible and, in a few short years, our streets have been cleared of horse conveyances and crowded with motor-vehicles; such engines are coming into use everywhere and have enabled us successfully to perform the feat which Dædalus vainly attempted—we even talk of flying from New York to London, across the vast Atlantic, to spend the week-end. The cyanide process has been introduced into gold-mining and is enabling us to unearth a fabulous wealth; a vast array of gorgeous colours has been produced, and Dame Nature so outwitted that we make indigo and madder out of the tar which in old days was put only upon fences; Pasteur's work has made Listerism possible, so that nothing is now beyond the surgeon's art and bacteriology is become the handmaid of preventive medicine and sanitary science; not only paper but a silk is made artificially from wood-pulp and the finest of scents are conjured out from all but waste materials. A multitude of other discoveries of practical value might be referred to.

Not so long ago, when scientific research was spoken of, the cry was always *Cui bono?* What's the good of it all? Now, no one has the patience to listen to a recital of the benefits accruing to mankind from its operation; for all the achievements I have referred to *are not the work of mere inventors* but primarily the outcome of scientific discovery: thus our modern command of electricity is very largely traceable to the labours of the great philosopher Faraday, who worked in an ill-lighted and cramped laboratory in the Royal Institution in Albemarle Street, London, with no other object than that of contributing to the advancement of knowledge.

Perhaps the greatest of all the scientific achievements of our time remains to be mentioned—the promulgation of the doctrine of evolution by Charles Darwin. Few perhaps can realise what this means for mankind, the intellectual advance it constitutes—that through it we have at last acquired full intellectual freedom and the belief that it rests with ourselves alone rightly to order our lives; that by it all dogmas have been undermined.

Science is come into being and has prospered only since freedom of thought was secured: on no other terms can it be. It is well that we should bear this in mind. The growth of numbers and of democracy may well involve a restriction of freedom in all directions—none are so intolerant as the ignorant.

If in science, to-day, we have something unknown to former civilisations, what is its influence to be on the future of the world, in particular on the future of the white people? If we are not to suffer the rise and fall which all previous civilisations have passed through—rather let me say, if the period of our fall is to be retarded beyond the period our forerunners enjoyed, it will be solely because we wield and use the powers science has put into our hands: not so much those of abstract science but the broad wisdom which the proper cultivation of science should confer; hence it is that I desire to urge the absolute importance of giving, through science, a place to the cultiva-

tion of wisdom in the State and therefore in education.

Clearly, two new forces are at work in the world: not science alone but also a broad and altruistic Socialism, both the outcome of the intellectual freedom man has acquired since the deposition of the Churches. The one is gradually leading us to base our actions upon knowledge and to be practical through the use of theory; the other is leading us gradually, though slowly, to have consideration for one another, to recognise how helpless are the majority, how greatly they stand in need of the guidance of the few who are capable of leading. But we shall need to order our Socialism by science to make it a wise Socialism. The signs are only too numerous that a wave of political despotism may come over us. Either, as time goes on, science will be more and more of service in guiding the social machine—or that machine will perish, from the very complexity of its organisation and the inability of the units to understand their place, to understand the need of subordinating their individual inclinations to communal interests; most important of all, to understand their inability to recognise and require competent leadership—for science is aristocratic in its tendencies: indeed, I shall claim that real science—wisdom—is for the very few.

With all the marvellous growth of achievement to which I have referred, there has been no proportionate growth of public intelligence. Our Admiralty, and to a far less extent our War Office, have called science into their service, but our public departments generally will have none of it. Even the elements of an understanding of the methods of science are not thought to be essential to the education of a Civil Servant; such knowledge is not required even in the highest branches of the Indian Service—no politician is for one moment supposed to need it: we are governed almost entirely by the literary spirit.

The spirit of the age, in fact, is in no way scientific, though ease and comfort are now provided on an unprecedented scale through the agency of science, the engineer acting as chief interpreter. Why do we still go naked and unashamed of our ignorance of "science"? One main reason is that the party in power is unscientific; but at bottom, I believe, the difficulty is a far greater one and probably innate in our disposition. It cannot well be supposed that man is by nature disposed to be scientific. The scientific fraternity, at any time, are, and probably always will be, but a small party—a set of freaks, sports from the multitude. They think and talk in a language of their own, as musicians do. The multitude may listen to them at times, with more or less of pleasure, as they do to music; but it is impossible, and probably always will be impossible, for the many to appreciate the methods and results of the scientific worker. Science, in reality, is a form of art and true artists are never numerous; moreover, it is admitted that they are born—like Topsy, they must grow, for they are not to be made in numbers. Our schools are for the most part in literary hands: and it would almost appear that literary and scientific interests are antagonistic, so unsympathetic has been the reception accorded to science by the schools.

Parenthetically, let me here deny the accusation not infrequently made by literary writers that the scientific fraternity are trying to oust literary studies from the schools. Nothing could be further from the truth. We are always craving for better literary training; our complaint is that the methods and subject-matter of literary training are far from being properly developed and, especially, that English is neglected in the schools. Huxley stated the real situation in saying, "Science and literature are not two things but two sides of the same thing."

The rise of science is due to the introduction of the experimental method. Mr. Balfour, in arguing, as he has done recently, that science rests upon many unprovable postulates and therefore does not differ in method from metaphysics, has made assertions which cannot be allowed to pass as correct. True science rests wholly upon fact and upon logic: all else is mere provisional hypothesis—a garment we are prepared to put aside at any moment if cause be shown. We are well aware that human nature is always intervening to spoil our work; it is human to err and false doctrine may easily occupy the attention for a time, but we are fully conscious of our limitations and prepared to admit them, whilst we feel that we are ever advancing towards security of knowledge.

The method of science, indeed, is the method of the Chancery Court—it involves the collection of all available evidence and the subjection of all such evidence to the most searching examination and cross-examination. False evidence may be tendered and for the time being accepted; but sooner or later the perjury is discovered. Our method, in fact, goes beyond that of the courts: we are not only always prepared to reconsider our judgments but always searching for fresh evidence; we dare to be positive only when, time after time, the facts appear to warrant a definite conclusion. But there are few instances in which we have travelled so far. The Newtonian theory of gravitation, the Daltonian theory of atoms, are two striking examples of generalisations which fit all the facts, to which there are not known exceptions; should any exception be met with we should at once doubt the sufficiency of such theories. In cases such as Mr. Balfour has discussed—the problems of metaphysics and of belief—experiment and observation are impossible: we can only resort to speculative reasoning; our belief, if we have one, is necessarily founded upon intangibilities and desires.

> There was a door to which I found no key:
> There was a veil past which I could not see;
> Some little talk awhile of Me and Thee
> There seemed—and then no more of Thee and Me.

The awful problem before us at the present time is to decide which direction we will take, to what extent and in what way we have the right to teach things which transcend our knowledge; the way in which truth lies may be clear to some of us but can never be to the majority. Those who wrap up such matters in a tangle of words are not helpful, to say the least. However mellifluous the terms of Bergsonian philosophy may be, they do not bear analysis when the attempt is made to interpret them; their effect is merely sensuous, like that of cathedral music.

But in order that she may lead, science must herself set an unimpeachable example—far too much that is now taught under the guise of science is pure dogma; in fact, the philosophy of the schools is mostly dogma. The true legal habit of mind is insufficiently cultivated and but rarely developed even among scientific workers—our logic is too often imperfect. In science, as in ordinary life, party politics run high and scientific workers are usually, for the time being, party politicians. We are too often crass specialists, always very human: indeed, whatever the lines along which evolution has taken place, they cannot well have been such as to favour in any considerable degree the development of the proclivities which distinguish the scientific inquirer: time after time, doubtless, he has been knocked on the head.

The difficulties under which science labours in our schools are partly internal, partly external. Tradition and the type of mind of the average teacher favour

set lessons and literary study by blocks of learners; the extra cost of the work is considerable, when the expense of the special requirements is taken into account; more time and more individual effort are demanded both from teacher and from taught; freedom is hampered by the need of considering the requirements of external examinations; finally, the universities have done but little to help, and though the schools have more or less unwillingly recognised that there is some value in scientific studies, in consequence of the persistent demands men such as Huxley have made, more especially because it is seen that there is money in them, none the less there is still no real demand for them on the part of the public. Of this and, in fact, of nearly all the real problems of education the public are too ignorant to be judges.

Having been more than forty years not only a teacher but also a student of students and of teachers, of educational methods, and of the conditions under which teaching is carried on, I have been led to form very definite opinions, the more so as I have been able to regard the problems not only from the pedagogic side, but also from that of the chemist and biologist—with some knowledge of the mechanism.

My view—and it is one that I desire to press to a logical conclusion—is that we must recognise that human ability is not merely a limited quantity but that it varies enormously not only in quantity but also in quality: the human orchestra contains a great variety of instruments differing in tone and range, but nature, like man, makes few instruments of superlative excellence, a vast number of very poor quality and only a moderate proportion of serviceable type. If science can tell us anything, it is that the democratic and republican ideal of equality is the veriest moonshine—a thing that never has been and never will be. And education can do very little to alter the state of affairs: it cannot change the instrument, at most it can develop its potentialities, and it may easily, by careless handling, do damage to the working parts. To take a special case, of interest at the moment, no contention is less to be justified, I believe, than that which has been put forward frequently, of late years, on behalf of women—that their disabilities are in no small measure due to the fact that we have neglected their education: give them time to educate themselves and they will be as men in all things. Years ago, at our Stockport meeting, I ventured to express the difference by saying that woman is not merely female man but in many respects a different animal: the two sexes have necessarily been evolved to fulfil different purposes. Nothing is more instructive in the history of modern educational progress than the fact that women have asked merely for what men have: at the universities they have attended the men's courses; not one single course have they demanded on their own account. Higher teaching in relation to domestic science so-called has only been thought of very recently and mainly because men have urged its importance. Most serious and, I believe, irreparable injury is being done to women, in London especially, by forcing them to undertake the same studies and to pass the same university examinations as the men: and the damage is done to the race, not merely to individuals, as the effect of education, whether direct or indirect, is clearly to diminish the fertility of the intellectual. Some day, perhaps, when the present wave of selfishness has passed over us, a rational section of women will found a woman's university where women can be taught in ways suitable to themselves without injury to themselves. In saying these things, of course, I am laying myself open to the charge of narrowness—in deprecation I can only say, that what we are pleased to call education is, for the most part, so futile in substance and in its results that I shall not mind in the least if I am accused of decrying it: in my opinion, we shall all be better without most of it, men and women alike. So far as so-called intellectual education is concerned, learning to read seems to me to be the one thing worth doing: at present it is the thing most neglected in schools.

To develop a rational system, we need to take into account man's past history and to apply evolutionary and biological conceptions. Education, as we know it and practise it, after all is a modern superstition—something altogether foreign to the nature of the majority of mankind; it is based on the false assumption that we can all be intellectual; whereas most of us can only use our hands. But the schools neglect hands and attempt the impossible by trying to cultivate non-existent wits. Man is doubtless pretty much what he was, and it is useless trying to make of him what he has never been.

We are seeking to educate all. What does this mean? Practically that we are seeking to teach all to read. But when they have learnt, what are the majority to read—what will they care to read? At the schools for young gentlemen, the reading taught hitherto has been mostly the reading of Latin and Greek. We know the result—the number of persons above school age who can and do read either language is negligible. Some of us learn French, scarcely any learn German, Spanish is all but neglected: when, therefore, we visit the Continent of Europe or South America we can only mumble a few words of the language of the country, and usually allow the foreigner we visit to speak broken English for us: few of us read his literature.

The vain attempt is made to put us in touch with the past but no real effort is exerted to bring us into contact with the present. We have not yet taught English in our higher schools, but are beginning to think of doing so—to this end, we are urging that attention be paid to so-called classical literature, forgetting, of course, that for the most part this was written for grown-ups and not as food for babes of school age.

The difficulty is still greater in the case of those who have only passed through the elementary schools—the literature that will appeal to most of these will be very limited in scope. Our newspapers show pretty clearly what will go down: not much—but it represents what is going on in life. In London, when the theatres are under discussion, it is often said that people want to be amused, not instructed; to cudgel our dull brains is a dull business to most of us. It seems to me that this doctrine should be applied more than it is in the schools. At all events, we shall do well to remember the words of the wise pundit in Rudyard Kipling's "Kim": "Education—greatest blessing when of best sorts—otherwise no earthly use."

To discover the best sort for each sort of student is our difficulty—who will do it? Here comes my point. Not the present race of schoolmaster or of educational authority. By placing classical scholars in charge, we seem unconsciously to have selected men of one particular type of mind for school service—men of the literary type; and this type has been preferred for nearly all school posts, mainly because no other type has been available, this being the chief product of our universities. Such men, for the most part, have been indifferent to subjects and methods other than literary—I verily believe not because they have been positively antagonistic or lacking in sympathy, but rather because of their negative antagonism: of an innate ability to appreciate the aims and methods of any other school of thought than their own, especially on account of their entire

ignorance of the experimental method. I believe, moreover, that the difference is fundamental and temperamental, not to be overcome by training. Oxford, owing to the bait of its classical scholarships, seems to have attracted an entirely peculiar type of ability and to stand alone in consequence; at Cambridge, owing to the hold obtained by mathematics, the field has been divided, but the mathematician, in his way, is often as unpractical by nature as the classic; fortunately, of late years, owing to the rise of the medical school and that of natural science, other elements have been introduced and the university has a future of infinite promise in consequence, if it will but realise that its primary function is to inculcate wisdom rather than to give purely professional training.

Sympathy is only begotten of understanding; the literary type of mind apparently does not and cannot sympathise with the practical side of modern scientific inquiry, because it has neither knowledge of the methods of experimental science nor the faintest desire for such knowledge.

We need a more practical type of mind for our schools. Pessimist though I may appear to be, having watched with close attention, all my life, the great struggle that has been going on in and between schools—having had the great good fortune also myself to be one of the early workers in the province of technical education, and having been associated with the development of one of the greatest of our boarding schools (Christ's Hospital)—I am, of course, aware that very great progress has been made, and am, in every way, hopeful of the future in store for those who are unaffected by present prejudices. In my experience, the men to whom the progress has been due have, in all cases, been trained in a broader school than that of Oxford; the few escapes from Oxford who have been successful reformers have been the exceptions which prove the rule, as they have shown themselves to be gifted with practical instincts: to such men the Oxford literary training has been of extreme value. Oxford will not gain its full value until all types of ability are represented in fair proportion by its students, not one almost exclusively. When this step is taken, the incubus of the Oxford spirit will no longer be upon us: it will then be possible for us to regard education as "a preparation for life"—a formula often used but usually honoured, hitherto, in the breach, rarely if ever in the observance, in our schools.

There must be no misunderstanding. The representatives of literary training rely chiefly on a past into which it is well not to look too closely and must always work with borrowed capital in the days to come: our side has no distant past worth speaking of, but is hopeful of a glorious future, in that it will always be adding to its knowledge; we desire to do their party all possible justice, and shall ever be in need of their assistance and more than grateful for the service they render us; but it must be war to the knife if they will not recognise that, in a progressive age, they cannot lead any longer, that we shall decline to put up in future with the conceit and narrowness of outlook of the classical scholar.

The argument I have applied to the teacher is equally applicable to the taught—boys and girls, indeed students generally, are of different types; they have different orders of ability and cannot be treated as if all were alike. In the beginning, we may tempt them with all sorts of scholastic diet, but only, in the main, in order to discover their aptitudes; when these are found, they should be the main line of attack. In saying this, I am not arguing in favour of extreme specialisation but against time being wasted in attempting the impossible. Some of us can learn one thing, others another: the schools try to force too many into one mould. It is essential that we should try to lay certain foundations but useless to proceed when we find that some of them cannot be laid.

This doctrine is applicable especially to the selection of scholars and to the training of teachers and of evening-class students. We select our scholars almost entirely by literary tests—the result is that we select persons of literary aptitude rather than those gifted with practical ability for every kind of service: like necessarily breeds like. By insisting on "grouped courses" we too often oblige students to take up subjects to which they are incapable of paying attention with profit: most of us, probably, have found out that there are many subjects which we simply cannot learn, try as we may.

My own experience with students has satisfied me that they not only vary in ability but that the different classes are of very different types of mind: the engineer tends to be constructive but not analytical; the analytical introspective habit of mind is more highly developed in the chemist; the biologist rarely has mathematical proclivities. It is useless to attempt to teach all in the same way, and many can learn only very little.

The explanation of Huxley's failure to forecast the future of science lies, apparently, in the fact that men generally *are not* attuned to her ways. I am inclined to think that the "mere man of letters" *will continue* to ignore and despise science—he will lack the peculiar mental capacity to assimilate scientific teaching. Only the few will rise to a proper understanding of the mysteries and be masters of their subjects, though many may be trained to be skilful mechanics.

The extent to which the multitude can receive instruction is a matter of primary importance. If, as Huxley has said, the greatest intellectual revolution mankind has yet seen is now slowly taking place by the agency of science—if she be teaching the world that the ultimate course of appeal is observation and experiment, not authority; teaching it the value of evidence: then must we strive to teach all, in some measure, what constitutes evidence, what observation and experiment are.

I believe much can be done in this direction, having made the attempt with hundreds of unwilling students in my time, students of engineering who had not only made up their minds that they were not going to learn chemistry as it was not their subject, but were incapable of ever entering into the spirit of the work—one of my sons was amongst them. At an early period, having realised that it was useless to waste my time and theirs in the struggle, and that it would not help them in the long run, to give them chemical tips which they lacked the sense to appreciate and to apply, I made up my mind, therefore, that it was desirable instead to develop any detective or inventive spirit that might be in them, so advised them to read detective stories instead of a text-book and ask themselves what the stories taught them: how the detectives set to work. Their attention was secured by urging them also to think what would be their position, later in life, when they were called upon to act for themselves and to get new knowledge for themselves, if they had not learnt to think for themselves. We have then set them to work to solve a series of problems in the laboratory. The course, in fact, was a combined laboratory-lecture course, the lectures being on and always subsequent to the laboratory work. In not a few cases, in after years, when I have met old students, they have told me spontaneously that, much as they had objected to the pressure put upon them, our insistence on their learning to do something themselves had proved to be of extreme value. Long experience has convinced me that anyone who has once learnt to make simple measure-

ments and observations and to ask and answer a definite question experimentally is on a different mental and moral plane from that occupied by those who have had no such training.

Such teaching is possible even in elementary schools—given competent teachers; but a new race of teachers will be required to carry the work into effect, should it be decided to make the attempt at all generally.

The great mistake that has been made hitherto is that of attempting to teach the elements of this or that special branch of science: what we should seek to do is to impart the elements of scientific method and inculcate wisdom, so choosing the material studied as to develop an intelligent appreciation of what is going on in the world. It must be made clear, in every possible way, that science is not a mere body of doctrine but a method: that its one aim is the pursuit of truth.

If we are to progress in these matters, a system must soon be developed which is broader and better than that under which we now muddle along—at present the real problems of education are all but neglected; even if the official mind were capable and desirous of promoting progress, the work of administering rules and regulations—of keeping the machine going—is so great that no time is left for thought.

We have seen the error of our ways sufficiently to give up payment by results and are all but ashamed that we were ever misled by Robert Lowe to adopt such a soul-killing policy. But none the less our entire educational system is still in the grips of commercialism, and, in this respect, as a nation, we stand alone, I believe. Scholarships, prizes of one kind or another, examinations are the perpetual feast of British education. Examinations, in fact, are a regularised and very lucrative branch of industry—mostly in the hands of certain firms who diplomatically shelter themselves under the ægis of this or that educational body; but the universities are the greatest sinners. Valuable as examinations may be within certain narrow limits and for certain definite purposes, there is little doubt that our general ignorance is in no small degree determined by our worship of the examination fetish. So long as the system prevails, the education of our youth will not be in accordance either with their capacity or their requirements but on lines corresponding to those by which prize cattle are raised for show—they will be trained to develop some specially catching point.

The examinations are an inheritance from the literary rule. It is possible to test on paper whether a man be "well read," but faculty as distinct from capacity cannot be so determined. What is worse, by forcing students to commit a large body of doctrine to memory, the attention becomes fixed merely upon what others have done and little time or inclination is left them to acquire a knowledge of method—the faculty of thinking for themselves and applying their knowledge. No class suffers more seriously than medical students under the system—their preliminary training is all but entirely didactic, and the time spent upon it all but wasted; we need not wonder that medicine has made so little advance, the practitioners being in no way trained in the use of scientific method.

To improve our system we need to get rid of our blind British belief in "men of affairs," especially in the "man of business," so-called, really the man of commerce, as persons capable of ordering everybody's affairs and everybody's business. The commercial man, the financier or the lawyer, would never think of calling us in to manage his proper business—why should he be thought competent to manage ours? Results show that he is not, as my argument in this address would lead us to expect would be the case.

No one will seek, for one moment, to minimise the progress made or fail to recognise that infinite credit is due to those who have controlled the work of education thus far; hitherto, however, progress has been made in providing accommodation and getting scholars to school and college: the art of teaching has made no corresponding advance—nor will it, I believe, until the onus is cast more directly upon the teachers and they are forced to exercise greater forethought in the direction of collective action—until they are placed in a position to be sole managers of their own affairs and called upon to row together as entirely self-chosen crews. At home, excepting at our ancient universities, "governing bodies" are paramount everywhere—not the teachers; and too often the sense of responsibility and power of initiative of the teacher are further diminished by the interposition of a principal, who may be a man of all affairs except that in hand—the work of teaching.

If the conclusion at which I have arrived be correct—that science is not for the multitude and can never be generally appreciated or even fashionable—in view of the part which it is clearly destined to play in education and in daily life, on account of its infinite and far-reaching influence upon our well-being—the responsibility cast upon the few representatives of science is very great; in support of our civilisation and in order that wisdom may prevail more generally, they must organise its forces effectively.

Whilst individuality is the mainspring of scientific progress, collective action is required to provide full and proper opportunity for the workers and to promote the success of their inquiries. At present, scientific workers are organised merely for the purpose of providing means of publishing the results of their studies, in no way either for defence or offence; our societies are not effective even for the purposes of debate and criticism. Thus, our chief English scientific society, consisting of some 500 members representative of all the various branches of physical and biological science, is little more than a rabble—its fellows are such individualists that scarce half a dozen of us can ever agree to work seriously together for a common purpose, and the irresistible influence we might exercise if we could be unanimous as to our objective is lost to the community. Most unfortunately, the society has no influence whatever either on political or on public opinion; it makes no attempt either to guide the public or to give dignity and importance to the cause of science in the eyes of the community. Its meetings are dull, and its belated publications by no means represent the scientific activity of its fellows. The presidents of the society have too often been appointed at an age when the propagandist spirit is no longer paramount, when they have no particular scientific message left in them to deliver. And they occupy the chair too long; this arises chiefly from the fact that however clear each one of us may be that individually he is fully competent to hold the office, we all agree in finding some objection to every name that is suggested; to overcome this difficulty a short tenure is desirable, so that the compliment can be paid and encouragement given to the various sciences in turn; no one should be appointed to such an office who is more than sixty to sixty-five years old, as most of us have used up our ideas and have lost our virility by that age. The other officers also hold their positions too long, but members of the council have far too short a life—consequently all the power is centred in the official body; attempts that have been made to organise the whole society in sections representative of the various sciences have always been defeated by the official party.

Unless our scientific societies can be made more

generally effective, if scientific workers are incapable of learning lessons from administrative life, it stands to reason that the collective interests of science and of the body scientific must remain unrepresented and unvoiced—to the great detriment of progress and of the public.

Science must be organised, in fact, as other professions are organised, if it is to be an effective agent in our civilisation; the problems pressing upon us are of such magnitude and of such infinite importance that we can no longer afford to be without wisdom.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—At Emmanuel College the exhibition of 50*l.* offered to a research student commencing residence in the present term has been awarded to L. Harrison, University of Sydney, for research in zoology. An additional exhibition of 50*l.* has been awarded to A. J. Philpot, University of London, for research in physics.

The authorities of the Imperial College of Science and Technology, including the Royal College of Science, the Royal School of Mines, and the City and Guilds (Engineering) College, have information of some three hundred of their present staff and students who are now serving with the forces of the Crown, but they have no means of knowing to what extent old members of the college have answered their country's call. They desire it to be known that they will be glad to receive from these or their friends any particulars in respect of service and welfare which may be of interest to the college. The registrar will be glad to deal with any matters of this kind.

In 1902 Dr. and Mrs. Christian A. Herter, of New York, gave to the Johns Hopkins University the sum of 5000*l.* "for the formation of a memorial lectureship designed to promote a more intimate knowledge of the researches of foreign investigators in the realm of medical science." According to the terms of the gift, says *Science*, some eminent worker in physiology or pathology is to be asked each year to deliver lectures at the Johns Hopkins University upon a subject with which he has been identified. The selection of the lecturer is to be left to a committee representing the departments of pathology, physiological chemistry, and clinical medicine, and if "in the judgment of the committee it should ultimately appear desirable to open the proposed lectureship to leaders in medical research in this country there should be no bar to so doing." The eighth course of lectures on the Herter foundation will be given by Dr. T. Lewis, lecturer on diseases of the heart, University College Hospital Medical School, London.

A copy of the current calendar of University College, University of London, has been received. It is arranged on the same general lines as in previous years and provides full particulars as to the preparation for various degrees of the University, the scholarships, and exhibitions available, the facilities for post-graduate study and research, lists of graduates from the college, and much other useful information. A full account is given at the end of the volume of the assembly of the faculties of arts, laws, science, engineering, and medical sciences held last July when Sir Archibald Geikie presided. The provost, Dr. T. Gregory Foster, in his report on the work of the session 1913–14, pointed out that the progress of the college in the matter of buildings and equipment, as well as of endowment, continues to be greatly advanced by the work of the equipment and endowment fund committee, which was established in 1902. The completion of the new school of architecture and the erection of the building for the department of applied statistics and eugenics, as well as that for chemistry, had been seriously hindered owing to the labour disputes—in fact, little work had been done on either building for more than twenty weeks. The delay caused the greatest inconvenience, and it has also largely increased the cost of both buildings. The college is still short of the funds necessary to complete the equipment of the new chemical laboratories, and is looking anxiously for a benefactor who will come forward and provide the amount yet needed. It is also looking for a benefactor who will give the funds requisite for the purchase of All Saints' Church and its equipment as a great hall for the college. Rapid development of the work in almost every department, the demand and necessity for the institution of new courses and new departments, make it more difficult every day, with the present accommodation, to progress with the times and to meet the new requirements. The provost then went on to announce the grant of 30,000*l.* by the London County Council, and said that at least another similar amount is necessary to complete the works in progress. The calendar also includes a list of the honours and appointments of former students and other persons connected with the college, and a comprehensive list of original papers and other publications from the various departments of the college during the session 1913–14.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, October 5.—M. P. Appell in the chair.—G. **Bigourdan**: The passage of Mercury across the sun of November 7, 1914. Precautions are suggested for the observations of the forthcoming transit of Mercury.—J. **Boussinesq**: Addition to a recent note on the coefficient of filtration with sand with more or less fine grains. Calculation of the coefficient for the heterogeneous sand used by Darcy in his experiments.—L. **Landouzy**: The auxiliary hospital of the institute, No. 265.—A. **Laveran**: Experimental infection of mice by *Leishmania tropica*. Twelve white mice were inoculated, eight males and four females. None of the latter were infected, but six out of the eight males developed the disease, of which full details are given.—E. **Delorme**: General considerations on the treatment of wounds received in battle. Disease in the French Army is almost non-existent, dysentery and typhoid fever scarcely reaching the figures in times of peace. The conditions under which the present campaign is being carried out differ from those in 1870 in that battles are carried on continuously for days and weeks, and prompt removal of the wounded from the firing line is impossible. It follows that by the time the wounded are received at the rear suppuration has in many cases already set in. This especially applies to wounds caused by shrapnell and fragments of shell, in which infection by earth is common. As a result cases of gaseous gangrene and tetanus are widespread, and necessitate a complete change in the surgical practice at the front. Hospitals must now be concentrated as close to the firing line as possible, and the work to be done at these hospitals is sketched out. The frequency of complications due to gaseous gangrene and tetanus is specially mentioned, and the best means of dealing with them close up to the firing line discussed.—Remarks by A. **Laveran** on the preceding communication. Suggestions as to the best means of using anti-tetanus serum.—Observations of M. **Roux**. Remarks on anti-tetanus serum.—Reply of L. **Landouzy** to the communication of E. Delorme.—E. **Maurant**: Ephemeris of the

Delavan comet, 1913*f*.—Charles **Rabut**: New projective invariants.—P. **Helbronner**: The complementary geodesic triangulations of the high regions of the French Alps.—Aug. **Chevalier** and Olivier **Rœhrich**: The botanical origin of cultivated rice.—M. **Rollet**: The extraction of German bullets and fragments of shell by the aid of a powerful electromagnet.

CAPE TOWN.

Royal Society of South Africa, August 19.—Dr. L. Péringuey, president, in the chair.—T. F. **Dreyer**: The morphology of the tadpole of *Xenopus laevis*. Among other conclusions the author states that the epithelium of the gill-slits is continued into the glottis, which is in support of the theory that lungs and gill-slits are homologous.—R. **Issel**: A morphological study of *Strongylus douglasi*, Cobbold. A description of the ostrich wire-worm. Although the parasite was discovered in South Africa more than thirty years ago and has considerable economic importance in view of the mortality it causes among ostrich chicks, this is the first complete description of the helminth. It has been found that the parasite has a buccal cavity armed with teeth. This and other details were overlooked in the original description.—W. A. **Jolly**: The interpretation of the electrocardiogram. An explanation of the form of the electrocardiogram in the human being, under normal and pathological conditions, was put forward, based on a study of the electrical changes in the simple and slowly contracting heart of the tortoise, isolated from the body and caused to beat by induction shocks.—W. von **Bonde**: On the crystallography of anatase crystals in the auriferous conglomerate of the Witwatersrand. An occurrence of minute anatase crystals in the Rose Deep Gold Mine was described recently by Dr. R. B. Young. A number of these minute crystals was sent to the S.A. College for crystallographic examination. This work was undertaken by the author. Chemical examination showed the presence of titanium in the mineral. There is, therefore, no doubt as to the correctness of Dr. R. B. Young's determination of the mineral as anatase. A stereographic projection of all the observed faces suggests the possibility that anatase has not the symmetry hitherto assigned to it. An extended examination of a larger number of crystals is in progress with the view of confirming or disproving this suggestion.—T. **Muir**: Note on the product of a special n-line determinant by its central minor of the $(n-4)^{th}$ order. In Mr. Roseveare's paper on a proof that every algebraic equation of the n^{th} degree had n roots, an equivalent was given for the product of a special n-line determinant by its central minor of the $(n-4)^{th}$ order, the equivalent taking the form of an aggregate of products of pairs of minors of the $(n-2)^{th}$ order. For such a product an apparently similar expression of a general character has been known for some time, but it is found that this does not include the form given by Mr. Roseveare. This latter form is considered and a generalisation of it is worked out.

SCIENCE AND THE STATE.

AT the present moment we as a nation are engaged in war; hundreds of thousands of volunteers are joining Lord Kitchener's Army; and it is evident that we are in for a long job. A forecast by the military correspondent of the *Times* of October 17 contains the following paragraph:—"This war, for us, has hardly begun. We have sent the point of our advanced guard into France to skirmish with the enemy. In the spring the rest of the advanced guard will follow, and somewhere towards the close of 1915 the main body will begin to come within view. We are not in any hurry."

With this prospect it may be fitting to inquire whether the best use is at present being made of the material at our disposal. We have multitudes of able-bodied young men willing to serve; there is no likelihood that the supply will fail; but at the worst, we can introduce compulsory military service. We can safely leave this question in the hands of our military advisers. There is also a great body of women in training as nurses, and a still larger body engaged in providing necessary warm clothing for the troops, and for the wounded. The unfortunate refugees in our country are being looked after, and in such ways the nation is rising to the demands thrust upon it. Everyone, in fact, is doing his or her best in individual and in organised effort.

But there is a class of our fellow-subjects which has as yet, so far as we are aware, not been organised. That is the Fellows of the Royal, the Physical, the Chemical, and the Engineering Societies. In their own particular provinces they are the pick of the brains of the country. This war, in contradistinction to all previous wars, is a war in which pure and applied science plays a conspicuous part. Has any effort been made to coordinate the efforts of the devotees of physical, chemical, and engineering science, so that they may work together at what for us is the supreme problem of all—how to conquer the Germans? For if we fail, civilisation as we know it will disappear. Democratic rule will have to yield to a military oligarchy. It was pointed out in an article in NATURE of October 8 how the originality in science of the Germans has decreased during the past generation, in spite of their enormous output of literature; this is to be attributed, no doubt, to the restraining influence of a military despotism, which has pervaded all aspects of their life. But in the design and manufacture of their war-material they have worked incessantly for years in their usual methodical manner, trusting rather to myriads of experiments than to the utilisation of original thought, which is for them in a great measure lacking.

The problems which at the present moment require the help of our scientific men are varied and numerous. Our first efforts must be to aid our military forces in suggesting and supplying them with all kinds of appliances and material of which they can make use in vanquishing the enemy and in defending our shores. We know, of course, that expert advisers have been attached to our ordnance factories, to our navy, and to our air-service for years, who have doubtless done much in preparation for the fierce struggle now in progress. But in war, *every man* who has special knowledge of physical, chemical, and engineering problems which confront the authorities responsible for the conduct of the war should be summoned to do his best.

It is not to be expected that under the enormous pressure at which they are working, the authorities of the War Office will have time or strength to effect an organisation such as is here suggested; to create such an organisation must be the duty of the councils of the chief scientific societies and of the British Science Guild; they must offer voluntary aid. A practical method of carrying out this recommendation would be for each council to consider in what way help can be given. It is for the Royal Society to set the example; among its fellows are to be found the *élite* of scientific men, belonging to all the scientific societies. A number of committees should be appointed, small at first, but with power to add to their number; each committee would draft out lines on which its members might advantageously work, and the committees might be strengthened by adding fellows or members of other societies, known for their special acquaintance with the conditions of each particular problem. Such services would, of course, be voluntary, and should be considered as one contribution of men of science to the relief of national needs.

It may be contended, however, that bodies of men such as those suggested have not the practical experience necessary for putting those of their ideas which promise useful outcome into a shape required for present emergencies. This contention, if it should be made, has little weight. There is much contact between those who have devoted their lives to the advancement of the

domain of pure science and those who have interpreted its results in practice; not so much, perhaps, as might be desired, but enough to make it possible to enlist the services of practical engineers, electricians, and chemical manufacturers in bringing to a practical issue any ideas which may commend themselves. Indeed, such men as might serve on the committees might do much to organise the efforts of manufacturers, so that no overlapping should occur, and in such a manner that the utmost efficiency should be secured.

It would be well, too, that some means should be adopted whereby these committees should come into contact; an engineering problem, for example, often requires co-operation from the physicist or chemist for its successful solution. Such co-operation, however, should not be difficult to arrange for.

We referred last week to the publication of a reasoned statement by British scholars, as a reply to a manifesto by German professors. This is all to the good; but we need action as well as words. Action is being taken by the Master of Christ's College, Cambridge, and the secretary of the Appointments Board of the University, to form a committee of members of that University to advise the "Entente Trade League." Here, again, is an effort in the right direction; but it cannot be too strongly emphasised that WE ARE AT WAR, and the first duty of all men of science must be to organise, and to place their services unreservedly at the disposal of our War Office.

In this hour of national emergency there is no time to be lost. We cannot all be soldiers, but we can all help, we men of science, in securing victory for the allied armies. Every day lost means the destruction of a number of our fellow-countrymen and of our allies, and the sooner we co-operate for the good of the nation the sooner will the war be over.

CROPS, STOCK, AND SOIL.

(1) *The Natural History of the Farm: A Guide to the Practical Study of the Sources of Our Living in Wild Nature.* By Prof. J. G. Needham. Pp. 348. (Ithaca: The Comstock Publishing Co., 1913.) Price 1.50 dollars.

(2) *Investigation into the Disease of Sheep called "Scrapie" (Traberkrankheit; La Tremblante): With Especial Reference to its Association with Sarcosporidiosis.* By Dr. J. P. M'Gowan. With an Appendix on a Case of Johne's Disease in the Sheep. (Edinburgh and East of Scotland College of Agriculture.) Pp. ix + 116. (Edinburgh: Wm. Blackwood and Sons, 1914.)

(3) *Die Typen der Bodenbildung, ihre Klassifikation und geographische Verbreitung.* By Prof. K. Glinka. Pp. iv + 365. (Berlin: G. Borntraeger, 1914.) Price 16 marks.

(1) PROF. NEEDHAM'S "Natural History of the Farm" is one of those books that could only be written in America, where individuality of outlook is allowed, not only to a professor of limnology, but to all who are engaged in doing anything with agricultural students. For it is recognised that the methods must not become stereotyped and that every teacher should have his own way of doing things. This book is a combination of natural history and nature-study, with much fluent writing about the joy of communing with nature and the things that really count in life; the chapters are ushered in with quotations from Robert Burns, Ecclesiastes, Whittier, Micah, etc., and along with the fluent writing is set a practical exercise. Anyone who knows the American student, with his (and especially her) capacity for taking things seriously, will realise that a book of this kind will get its chance, and that the intention of the author will be duly respected. His aim is not so much to teach as to arouse such interest in country life that men and women shall remain in the country and not migrate to the town. We have the same problem ourselves, and may yet have to deal with it in the same manner.

(2) Dr. M'Gowan's book deals with a disease in sheep which has become widely known in some of the border counties during the last few years, especially in Roxburghshire and in Northumberland. The symptoms exhibited are persistent itching without any evidence of "scab," a gradual emaciation, but no diarrhœa or loss of appetite, a change in gait and a weakening of the muscle power; the disease is almost universally fatal. It is known in the north as "scrapie," but it appears to be identical with diseases described by older writers as rickets, goggles, shakings, cuddie trot, etc., and with "la tremblante" and the "traberkrankheit" of the Continent.

The author's investigations lead him to believe that it is caused by a heavy infection of the sheep with a protozoan parasite (sarcosporidium). He attributes the infection to the system in vogue in the north of breeding from the two-year-old ewes for the purpose of keeping up the ewe stock; he finds no evidence that the disease is spread by the ram. His reasons for attributing the disease to the sarcosporidium are (1) that the sarco-

cyst is always present in the skeletal muscles of affected sheep in large numbers, the more advanced the disease the larger being the numbers present; (2) the itching can be reproduced in rabbits by infection with sarcosporidial emulsions. It would be more satisfactory to have the complete demonstration with sheep instead of with rabbits; but no doubt this will come. In the meantime Dr. M'Gowan has to admit that he has no treatment to suggest, but recommends that the affected animals should be sent to the butcher before their case has become too serious, whilst the ewe stock should be kept up from the progeny of animals older than two years. Inbreeding also should be conducted with great caution.

(3) The study of the formation of the soil owes much to the Russian investigators Dokutschajeff, Kostytscheff, Sibirceff, Glinka, and others, and in this volume we have a very convenient summary of what they have done, and a good description of Russian soils by one of the best of the modern Russian workers. One of the troubles of the past has been the lack of a widely-accepted system of classification; several have been proposed, but none has been universally adopted. It is largely to the Russian investigations that we owe the possibility of a definite system; their insistence on the necessity for more adequate recognition of climatic factors has widened our views on the subject and enabled better groupings to be made. More survey work has still to be done before a final classification can be set up, but in the meantime the scheme outlined in the present book is of distinct value.

The author recognises two great groups of factors in soil formation: internal factors—such as the composition of the rock—and external factors, such as climate. He accordingly sets up two great classes of soils: endodynamomorphic, in the formation of which the internal factors have predominated, so that the properties of the soil are governed by the properties of the originating material; and ectodynamomorphic, where the external factors predominated, the influence of weathering and transporting agents, the climate to which the soil has been exposed, etc., having outweighed the effect of the composition of the original material in determining its properties. Examples of the first are the various black soils containing calcium carbonate, which he calls rendzina soils. These include our fen soils, the black earths (tschernosem, etc.). The ectodynamomorphic soils are subdivided into six groups according to the amount of washing they have received during the process of formation. The tropical "laterite" soils come at one end of this chain and the alkali soils at the other. There are, of course, transition forms, but in the main the world's soils fall fairly easily into the scheme. The book will be read with much interest by all students of the soil.

E. J. R.

THE EVOLUTION OF PHILOSOPHICAL THOUGHT.

Greek Philosophy. Part i, Thales to Plato. By John Burnet. Pp. x+360. (London: Macmillan and Co., Ltd., 1914.) Price 10*s.* net.

THIS is the second volume of a series by various writers entitled "The Schools of Philosophy," and edited by Sir Henry Jones, professor of moral philosophy in the University of Glasgow. The author states in the preface that his chief aim has been to assist students who wish to acquire a first-hand knowledge of what Plato actually did say in the dialogues of his maturity. He should be eminently fitted for this task, as he was Taylorian scholar in 1885, and ever since he has kept himself immersed in Greek literature.

In a footnote on the last page he states that he has edited the whole text of Plato, and the usual books of reference give a list of his other works, which are all connected with the Greek classics. This footnote, however, like a woman's postcript, contains the key to his mind, as it begins by saying that he was drifting into a "hopeless scepticism," from which apparently he now believes himself convalescent. Yet he begins the introduction with the paradoxical words: "No one will ever succeed in writing a history of philosophy." The catalogue of the British Museum provides one horn of the dilemma, and his latest book supplies the other. It deals with philosophers, or with some of the greatest and earliest, but it contains no information likely to assist the rising generation of undergraduates and philosophers in ascertaining what were the ideas these ancients were groping after. Only by a supreme effort of the maieutic art could a student ascertain from the book itself that in physics one of their greatest stumbling blocks was the equation of motion of a falling raindrop, $\frac{dv}{dt}=g-g\left(\frac{v}{H}\right)^n$ which they only had under observation when v was equal to H.

The discussion of this problem is noticed by Duhem in his article, p. 272, "Roger Bacon et l'horreur du vide," in the commemoration volume of Roger Bacon essays just published. The word "natural" attached to motion always presupposes a gravitational cause. The horror of the void arises from the metaphysical notions derived from Aristotle now embedded in scholastic or neo-

scholastic philosophy where "form" combined with "matter" (or Clerk Maxwell's æther) produces "substance" which in turn supports "accidents," which latter alone constitute the subject-matter of inquiry of modern physical science. They give rise to the three indefinables of nature, weight, time, and space. A void by definition contains no "matter," and therefore no "accidents," and is without dimensions. It is dismissed by Aristotle as an absurdity, as a hole in the æther.

As regards the religious philosophy of the Greeks, they were groping for the metaphysical essence of "Actus Purus," or of God. Whether or no the chief attributes of God are explicitly known to every modern, it cannot be denied that they are enshrined in the English language, and form the subject of some of the finest passages of the English classics. To name a few of those not to be found in the Greek classics, self-existence, infinity, unity, simplicity, immensity, omnipresence, immutability, eternity; it was of these that Plato said, when asked as to his doctrine of the Good, "There is no writing of mine on this subject, nor ever shall be," words suitable for those times before the power that created the universities of Paris, Oxford, Cambridge, and eke St. Andrews, had come into the world.

Some hundreds of sentences in the book begin with the word "now," and on p. 118 we are told that Hippias's curve, the quadratrix, would solve the problem of squaring the circle by a geometrical construction if it could be mechanically described. It is well known that Hippias himself made an instrument to draw his curve, and any schoolboy can imitate it. J. H. Hardcastle.

A NORTH AFRICAN RACE.

The Eastern Libyans: An Essay. By Oric Bates. Pp. xxii + 298 + xi plates. (London: Macmillan and Co., Ltd., 1914.) Price 42*s.* net

IN this excellent monograph Mr. Bates has collected a rich store of facts relating to the ancient Libyan people, which will be of the greatest value to workers in many fields. Besides the strictly archæological side of his subject, he has also treated fully the physiography of the region, so that the whole subject is given a definiteness and actuality which may be imitated with advantage by writers on similar subjects.

The region over which these people formerly moved is a wide one, and eastern Libya, with which this work is concerned, extends from the west of Tripoli to the Nile Valley. This part of Africa is crossed by many routes of caravans and travellers, yet few portions have been seriously examined by qualified investigators, but from the material available and from his own observations Mr. Bates has produced a very accurate account of this area, which geographers will find of real worth.

In treating of the ethnology and ethnogeography the author has been able to come to certain conclusions from a discussion of Egyptian, classical, Berber, and Arabic data, which seem to indicate that the Libyans were pushed back from the seaboard, and from the oases to the westward, and the outcome of this was the periodical aggressions on the Nile Valley whenever that country was weak and the prey of contending factions.

Living in an arid region where vegetation was of the scantiest, the Libyans were nomadic, as are their modern representatives, and the few representations of them which exist in their deserts are largely scenes of hunting or of cattle. Routes followed by caravans, then as now, ran north and south rather than east and west, and even in early times the Libyans were in connection with the Sudan to the southward, and received the produce of that region, doubtless by means of ox-transport until the camel was introduced.

The Egyptian records are closely discussed in order to derive a clear idea of the social development of the early Libyans, and while holding that they were regularly and extensively polygamous, the author contests the charge of promiscuity which classical writers have brought against them. Their dress, and their material culture and art, is fully described and illustrated, so that the meagre records of these primitive people are made to furnish a fairly adequate picture of the state of civilisation at which they arrived. Their possessions were few and of a simple type, as is to be anticipated among a nomad people, and metals were rare, stone implements being principally used in their arrows, javelins, etc.

A careful summary of their history, drawn from all available sources, completes a most valuable monograph for which the material has been largely collected by the author in the field, and thereby it has gained a reality and a truthfulness of colour to which a compilation can never attain. In an appendix Mr. Bates refers to the so-called "C group, Middle Nubians," of Dr. Reisner in the Nile Valley, and these he would class as a Libyan race which established itself there. Besides furnishing the anthropologist and the geographer with valuable data for their studies, the author by his careful treatment of place-names, has put at the cartographer's disposal material for improving existing maps of North Africa, and the map included in the volume might with advantage have utilised the information so given. H. G. L.

COLLECTED ADDRESSES ON HORTICULTURE.

The Horticultural Record. Compiled by Reginald Cory. Pp. xv+500+cxvi coloured plates+half-tone photographs. (London: J. and A. Churchill, 1914.) Price 42*s.* net.

THIS sumptuous volume very ably fulfils the intention of its author as set forth in his preface. For it forms a very complete record of the sayings and doings of the International Horticultural Exhibition, which was held in London two years ago. In it are contained the addresses, and much of the consequent discussions, which dealt with aspects and phases of horticulture in many and varied directions These contributions possess a permanent value, and Mr. Cory would have deserved well of everyone interested in horticulture had he done nothing more than bring these results of the exhibition together in a guise far removed from the formal and often rather repellent character commonly encountered in ordinary official publications. But he has done very much more, and the beautiful illustrations, both coloured and plain, not only add enormously to the attractiveness of the volume, but they give it a value which is permanent, and will secure for it a high place in the historical literature of the garden.

The names of those who were responsible for the main addresses provide a full and sufficient guarantee as to their authoritative character, and the addresses themselves may well be read, and re-read, by those who are interested in the particular departments with which they severally deal.

The International Exhibition succeeded in achieving much more than the mere display of concrete results of horticulture. It served as the opportunity for raising issues of great and wide-spread interest and importance. The legislative enactments connected with plant diseases, the problems involved in horticultural education, and other subjects, perhaps more directly horticultural were ably and fully discussed, and we have already begun to reap some of the harvest which was sown at Chelsea in 1912.

Too often, perhaps, the results which accrue from congresses of various kinds are altogether incommensurate with the amount of energy and material expended at the meetings, but this is not true of the one now under consideration. It is fitting then that the record should be a full one, and that it should be presented to the world in an attractive form. The author and the publisher have discharged their respective offices with skill, and we do not hesitate to express the opinion that the book is destined to occupy a high place in the literature of horticulture.

OUR BOOKSHELF.

On the Effects of Volcanic Action in the Production of Epidemic Diseases in the Animal and in the Vegetable Creation, and in the Production of Hurricanes and Abnormal Atmospherical Vicissitudes. By Dr. H. J. Johnston-Lavis. Pp. xii+67. (London: John Bale, Sons and Danielsson, Ltd., 1914.) Price 3*s.* net.

A FEW years ago the Royal College of Physicians of Edinburgh offered their Parkin prize for an essay with the above title, and they were fortunate in being able to award it to the late Dr. Johnston-Lavis, than whom no one could be found more competent to deal with the subject. Johnston-Lavis combined with his well-known familiarity with volcanic phenomena the experience gathered during many years of medical practice, in districts constantly subject to volcanic and earthquake paroxysms.

After giving a general account of the physical and chemical phenomena exhibited during a volcanic eruption, the author proceeds to detail and examine the exaggerated and often grotesque accounts given by many authorities concerning the terrible diseases that have affected human beings, and also animals and plants, during and subsequent to volcanic outbursts. Dr. Johnston-Lavis's general conclusions, after an examination of the whole question, are that while there is no *direct* relations between volcanic phenomena and disease, there are the following *indirect* ways in which epidemic disease may be caused or increased during or after volcanic eruptions:—

(1) The irritating and depressing effects of poisonous fumes on the eyes and throat.

(2) The disturbance of water-courses, leading to wells and surface supplies being infected from sewage; and the interference of the ventilation of houses by the accumulation of ejected materials.

(3) The moral depression from fear, with the hunger resulting from food-supplies being cut off, these causes being now recognised as rendering living beings less immune to infection.

That great atmospheric disturbances are occasioned by volcanic outbursts is admitted by all meteorologists.

Praktikum der Chemischen, Biologischen und Bakteriologischen Wasseruntersuchung. By Prof. O. Emmerling. Pp. vii+200. (Berlin: Gebrüder Borntraeger, 1914.) Price 7.20 marks.

As indicated in the title, this work consists mainly of a series of descriptions of the methods employed in the examination of waters. As is well known, the chemical methods employed in German practice differ in some respects from those in vogue here, and it is therefore interesting to be able to institute a comparison. Although several methods are frequently described for a particular estimation, little advice is given as to which is the best to employ, and occasionally insufficient attention is paid to the fact that very small amounts have to be estimated.

A sign of the times is the inclusion of methods

for the estimation of the radioactivity of mineral waters. A considerable amount of attention is paid to the biological, as distinguished from the bacteriological, examination, and a large number of excellent figures are given of the various species of organisms likely to be met with in waters of various types.

The least satisfactory section is that dealing with the bacteriological examination of water. In particular, the detection and enumeration of the *B. coli communis,* to which so much attention is paid in this country, is treated in an extremely inadequate manner.

Highways and Byways in Lincolnshire. By W. F. Rawnsley. With illustrations by F. L. Griggs. Pp. xx+519. (London: Macmillan and Co., Ltd., 1914.) Price 5*s.* net.

THIS book maintains the high reputation of the series to which it belongs. Mr. Rawnsley has throughout supposed the tourist to be travelling by motor, and has accordingly said very little about footpaths. Lincolnshire, he says, teems with splendid churches, and that is the first impression received after looking at the admirable illustrations which Mr. Griggs has provided. But attention is by no means confined to ecclesiastical architecture, for the book abounds in anecdotes, gossip, and quaint information. We read that Sir John Franklin, the famous arctic navigator, and Major James Franklin, who made the first military survey of India, were born at Spilsby in this county. On the road from Spalding to King's Lynn the author tells us he passed a field with an unfamiliar crop of stiff purplish plants which showed where the cultivation of *Isatis tinctoria,* the woad plant, which added so much to the attractiveness of our earliest British ancestors, was still kept going. Or, again, at Tothby a plague-stone is to be found, and we are given a bright account of how sufferers from the plague in the seventeenth century were fed without spreading infection. The book will appeal not only to Lincolnshire people, but also to all who love the English countryside.

Les Coordonnés intrinsèques. Théorie et Applications. By Dr. L. Braude. (*Scientia,* No. 37.) Paris: Gauthier-Villars, 1914. Pp. 100. Price 2 francs.

ALTHOUGH quite good in its way, this book does not present any very striking features. It may best be described as a collection of problems most of which could be worked out as exercises by any fairly good English mathematical student. Intrinsic equations are here obtained for the usual well-known plane curves, such as cycloid, catenary, equiangular, spiral, and they are applied to the study of associated loci such as roulettes, Mannheim's curves, pedals, or involutes and evolutes. In England this work is commonly studied in courses rightly or wrongly described as "advanced calculus," but it may be useful to teachers and others to have a book of reference in which the subject is treated separately and in greater detail than in our calculus text-books.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Accumulated Rainfall at Excessive Rates.

IN the *Monthly Weather Review* a table (No. II.) is regularly published giving accumulated amounts of precipitation when the rates equal or exceed :—

Duration	5	10	20	30	60 minutes.
Rate per hour	3·00	1·80	1·20	1·00	0·80 inches.

Unfortunately the headings and the entries are not consistent; and the purpose of the table is defeated by a tabular arrangement in which sense is sacrificed for space. The table misleads American meteorologists, even those of us familiar with the arrangement; and it is therefore not to be wondered at that the most eminent of climatologists, Dr. Julius v. Hann, read for a five-minute interval 4·19 in. of rain when the actual fall was 0·13 in. at Oklahoma, June 30, 1913 (*M.W.R.*, 41·7: 1129, July, 1913).

Prof. Hann directed attention in the *Meteor. Zeitschrift,* of which he is editor, to this remarkable rate (*Meteor. Zeits.*, vol. xxxi., part 4, p. 196), stating that it was the heaviest rainfall on record, and gravely adding that the rate, 21·3 mm. was most remarkable, and that it was scarcely conceivable that so much water could fall from the sky in five minutes.

Dr. Hann should not be held responsible for the error. A correction has been published in a recent number of the review, but few will see it, and in the confusion incident to the war it may escape general notice. We are likely, therefore, to meet the statement in years to come that official records show a rainfall of the rate given above.

With the hope of preventing future misunderstandings, I have appealed to the chief of the Weather Bureau to alter the table, and have further urged that now is an opportune time to abandon the use of inches in measurements of precipitation and use the millimetre. Is it not also high time that British rainfall was expressed, if not indeed measured, in millimetres?

Accumulated amounts at excessive rates are of interest to engineers, and it might be well to substitute for the present values, which are arbitrary and confusing, the following rational units :—

Duration ...	1	5	10	60 minutes.
Rate per hour ...	1	5	10	20 mm.

I add the heaviest known rainfalls and rates with the hope that some of the readers of NATURE will amend.

	Rate per hour	Actual duration of rate
Baguio, P.I., July 14, 1911 ...	49 mm.	24 hours
Campo, Cal., August 12, 1891 ...	219 „	80 minutes
Guinea, Va., August 24, 1906 ...	470 „	30 „
Curtea de Argrea (Roumania), July 7, 1889	615 „	20 „

ALEXANDER MCADIE.

Blue Hill Observatory, October 12.

Fizeau's Experiment and the Principle of Relativity.

SIR JOSEPH LARMOR has kindly pointed out to me that it is incorrect, in the interpretation of Fizeau's experiment, to assume that the velocity of propagation of light is the group velocity, so that I must withdraw

the conclusion drawn by me in NATURE of October 22, that Michelson and Morley's repetition of the experiment, when correctly interpreted, is in close agreement with the predictions of the principle of relativity. This being so, it may be worth while to direct attention to certain facts in connection with that experiment which render it quite inconclusive.

(1) On the ground of an experimental device for estimating the pressure gradient at different points of the tube, Michelson and Morley assume that the velocity along the axis is equal to 1·165 times the mean velocity. This is in sharp contradiction with the theory of the flow of liquid in a tube which shows that the axial velocity is twice the mean.

(2) The beam of light which traverses the tubes appears from the figures given to occupy a considerable fraction of the whole area of the tube, and is thus subject to a retardation in phase which varies with the variation of the velocity of the liquid at different distances from the axes. It may be shown that the retardation in phase of the resultant disturbance when brought to a focus is equal to that which would be produced if the velocity of flow were uniform and equal to the mean velocity over the part of the tube occupied. If this were the whole tube the result of applying these corrections would be to increase the result given by Michelson and Morley for the convection coefficient from 0·434 to 0·515. On the other hand, if the diameter of the beam were about 0·93 of the diameter of the tube the mean velocity would be so much greater that the convection-coefficient would be reduced to the theoretical value given by the formula of Lorentz, viz., 0·451. There is thus a possibility of general agreement, but the experiment is quite indecisive.

The announcement that Prof. Zeeman has repeated the experiments with great care and with monochromatic light and has succeeded in observing a dispersive effect is, therefore, of great importance, and his detailed results will be awaited with much interest (Amsterdam Proceedings, September 26).

E. CUNNINGHAM.

St. John's College, Cambridge, October 26.

Flint Fracture.

MR. LEWIS ABBOTT's letter in NATURE of October 22 is almost entirely irrelevant to the subject of my communication to NATURE of September 24. In this note I dealt solely with one form of flint fracture, viz., the large, flat, non-conchoidal fractures, surfaces which are produced by a certain type of "cleaving" blow, and pointed out how it is possible to determine the nature and direction of the fracturing-agent by the recognition of the fissures of varying size radiating from the point of impact. Mr. Abbott, however, states, these "are certainly not fissures"; but an examination of these markings upon a flint and a reference to the meaning of the word "fissure" in a dictionary will convince anyone that my description is correct.

The major part of Mr. Abbott's letter deals with subjects upon which my former note has no bearing, and though I agree that these are important and need investigation, yet it seems regrettable, if the problems they present were, as Mr. Abbott infers, in process of solution several years ago, that the knowledge already acquired at that time has not up to the present been laid before the scientific world. It is to be hoped that Mr. Abbott may be able to induce the collector who interviewed the late Sir John Evans to do so without delay.

J. REID MOIR.

12 St. Edmund's Road, Ipswich, October 23.

TOWARDS NATURE-STUDY.[1]

(1) PROF. ABBOTT'S aim is to give "a simple statement of the fundamentals of General Biology," both for the general reader and the laboratory student. He deals with both plants and animals, shifting his field so as to get the best illustrations. The main subjects discussed are—living substance, the primary functions, metabolism, growth, differentiation, development, variation and heredity, organic response, species and their origin. The book is well-illustrated and marked by three other qualities—an admirable clearness which points to teaching experience, a pleasant freshness of treatment which is in part due to the numerous references to recent work, and an all-roundness of survey, for almost every aspect of biology is at any rate recognised and illustrated. This third quality lays the book open to the disadvantage of sometimes saying too little, but most introductory books of this sort say far too much. But we should have liked, for instance, to know more about those sea birds which "lay their eggs on the bare rocks and pay no more attention to them thereafter."

(2) Prof. J. R. Ainsworth-Davis is a firm believer in the value of "nature-study" as a factor in increasing efficiency, and his book—an outcome of large experience—is meant to indicate how the subject may be best dealt with, especially in country schools. After clearly indicating how arithmetic, for instance, may be made vital in the country schools by being applied to actual problems, he proceeds to show this is even more essential in connection with nature-study. For this reason the book gives prominence to common plants and animals and familiar physical phenomena. In regard to the part dealing with plants and animals, however, it appears to us that the author falls far short of his counsel, telling too much and suggesting too little. It is good pemmican, but it is pemmican. In his introduction he protests against the "informational obsession," and upholds "the educational ideal";

but it seems to us that in the bulk of the book the author is informational with the best of them. But Prof. Ainsworth-Davis knows his own business, and while we do not think that his method (as regards living creatures) is the best, he has chosen it deliberately. We hasten, therefore, to say that he has produced a wonderful little book, clear, terse, and accurate, which will aid in their pursuit of natural knowledge those who combine good intellectual digestion with the inclination and opportunity to verify what they are told.

(3) It is interesting to find Drs. Boulenger, father and son, uniting their abilities and enthusiasm in the production of a guide to the study of the animal life of the seashore. The result is a delightful and effective book by which those interested can identify many of the littoral animals and get some trustworthy information about them. We confess to being surprised at the suggestion in the preface that there was a lack of a book of this kind, for Dr. Marion Newbigin's "Life by the Seashore" is an excellent and trustworthy guide, and Sinel's is also good. But there is no risk of exhausting the interest of the shore, and the book before us has a character of its own and pre-eminence in the excellence of its photographic illustrations, many of which are fascinatingly beautiful. That of the sea-horse (Fig. 1) is a good instance.

The authors tell their story in a clear and interesting way, which stimulates both observation and reflection. We read of the wrasses sleeping on one side, of the stickleback's nest and large eggs, of the sting of the weever, of paternal care among pipe-fishes, of the homing of limpets, of the boring of piddocks, of the shrivelling of the lobster's muscles before moulting, of the colour-change in *Hippolyte varians,* of the various sea-shore insects, of the cotton-spinner's sticky thread-like tubes, of the partnership between hermit-crabs and anemones, and of much more that makes us long to be back to the shore again.

(4) Another shore-book, to be strongly recommended, has been written by Mr. Elmhirst, superintendent of the Marine Biological Station at Millport. It is the work of an experienced naturalist who has written simply and clearly about what he knows well. He begins with the common seaweeds and works up to the shore-birds, and by exercising a wise restraint has succeeded in giving a luminous, not over-crowded, picture of the natural history of the shore. He has many interesting notes on the habits of animals, telling us, for instance, of the way in which *Echinus miliaris* dresses itself up till it becomes "a sort of moving scrap-heap," of the shrimp's rapid burying of itself, of the sea-spider (Pycnogonum) sticking its proboscis into an anemone and sucking up the juices through a filter, of the dog-whelk boring through a mussel, and of the starfish slowly forcing the same bivalve to gape. There are some very effective photographs, but the most striking feature of the book is to be found in the charming coloured pictures by Mr. William Smith. It seems to us very unpractical to put one of these beautiful sketches on the cover. If it is put there it should also be repeated inside the book.

(5) Mr. Westell believes in "a very real desire for a school-book on birds," and he has suggested twenty-four practical out-of-door studies, which he has wisely arranged in the order of the seasons. The "lessons" are conversational and socratic, and they suffer a little from the defects of these qualities. The conversation is occasionally thin, and the questions are sometimes fatiguing. But there is a pleasant temper in the book and a feeling of the open-air. The children who answer all

FIG. 1.—Sea-horse. From "Animal Life by the Sea-shore."

the problems set—some of them very educative—will certainly know a lot about birds. We think that the author should have taken more care with his English—especially in a book intended for schools. Thus we read: "One of the most remarkable episodes connected with the life-story of these aquatic birds is the provision which has been made for the young to be able to take care of themselves as soon as they are born." As the starling "hawks and hovers in the air," etc., "it presents a fine study of a familiar bird which adds a good deal of charm to the bird life near at

home." It is a pity that there are many of these awkwardnesses in this little book. But the book is well-conceived and on the whole sound. It is very effectively illustrated, and the multiple appendix, mostly devoted to practical matters, from observational outfit to the Wild Birds' Protection Acts, will be found exceedingly useful.

(6) Mr. Hall has provided a useful introduction to the study of British beetles—a study which only needs to be begun seriously to become an enthusiasm. The book has an introductory chapter describing the external structure of beetles, and another on their habits, as illustrated by the Green Tiger beetle, the large water-beetle, the burying beetles, the cockchafer, and so on. Apart from some hints on collecting and mounting, the rest of the book is devoted to terse descriptions of some of the commoner forms. These descriptions are quite effective, but we should like to have had more information in regard to habits. The coloured plates, which are on the whole very successful, will be of great service in identification. It seems to us very unpractical to put one of the plates on the cover. There are some interesting photographs, but that of the trachea of Dytiscus does not show the structure as it professes to do. We wish the book success.

(7) There is an intellectual discipline in nature study and the possibility of learning certain lessons which are for our good as citizens of the world, but perhaps the surest gain is simply an increase in our love for the country. If nature study does not lead towards this, there is something wrong. Holding this view, we have always a welcome for a book like Mr. Urquhart's "Odd Hours with Nature," which was evidently written with joy and sincerity. The author takes us with him on his every week walks, and we enjoy his company as he shows us the tree-creeper in the winter-woods, the supernumeraries (bachelors and widows?) of the rookery, the field where the hares fight, the trickery of the lapwing, the trustfulness of the young deer, the dipper walking on the bottom of the stream, and so on till we come back to a queen humble-bee disturbed in her winter retreat. There is nothing very profound in the author's studies, but they are the fruits of observation and reflection, written in excellent style, expressing a love of nature and contributing to its diffusion. We give an example (Fig. 2) of the well-chosen illustrations with which the studies are adorned.

FIG. 2.—In Stag Ground. (From "Odd Hours with Nature.")

(8) It is said that many people have been led by the pathway of photography to an appreciation of the beauty of the world, and the book of striking photographs of natural objects which has been published by the director of the "Urania" institute in Berlin should prove effective in this direction. It is a scientific picture-book, displaying some of the most beautiful objects in the world, many of which will be new and startling to most people. The album illustrates the exuberant decorativeness of Haeckel's Radiolarians, Medusæ, and Siphonophores; the gracefulness of Allman's zoophytes; the futurism of Lehmann's fluid crystals; the fascinating

beauty of calla-lilies, heaths, poppies, and ferns; the likeness between frost-flowers on the window-pane and the snow-laden forest-trees; the flower-like corals; the individuality of shells; the exquisiteness of hidden organic architecture; the conscious beauty of Argus pheasant and bird of paradise; and much more besides. Who is sufficient for all these things? The pages are too crowded to do full justice to the various pictures, the table of the beauty-feast is overloaded, but no one can fail to get an impression of subtle and exuberant beauty. The text accompanying the album consists of two essays. The first is by Haeckel, entitled, "Nature as Artist," and in it the veteran expounds his theory of a "plastic instinct" in protoplasm. Every organic product arises in accordance with physical and chemical laws, but it is none the less an expression of the "cell-soul." Many naturalists have said the same thing in different words! The second essay is by Dr. W. Breitenbach and deals with the universality of beauty in nature, its manifold expression, and the enrichment of human life which it may afford.

(9) We have nothing but praise for the Regional Survey which has been compiled and published by the Bournemouth Natural Science Society under the able editorship of Sir Daniel Morris. It is a model of what such a book should be—dealing with the topography, geology, zoology, and botany of the district, and not forgetting the works of man, both past and present. The society is to be congratulated on having so many members able to co-operate competently in a work of this kind; and those who have the good fortune to reside in an area with so many interesting features are to be congratulated on the possession of this excellent aid to a fuller appreciation of their opportunities.

(10) Prof. Bastian Schmid has done a useful piece of work in compiling a manual on the technique of natural science, and he deserves our thanks. The book had, of course, to be written co-operatively, for only experts could deal effectively with the great variety of technical methods now in use in nature study in the wide sense. Prof. H. Poll deals with zoological microscopy, Dr. H. Fischer with botanical microscopy, including bacteriological and mycological methods, Prof. P. Claussen with experiments in vegetable physiology, Prof. R. Rosemann with methods in animal physiology, Dr. C. Wagler with hydrobiology, Dr. O. Steche with collecting and preserving insects, Dr. Paul Kammerer with collecting molluscs and vertebrates, Prof. Schoeler with herbaria, Prof. B. Wandolleck with preserving animals and setting them up, Prof. F. Urban with vivaria, Dr. P. Esser with school-gardens, Dr. H. Fischer with the microscope, Prof. B. Wandolleck with photography, Prof. R. Fricke with excursions, the editor with practical arrangements and devices in schools and colleges, Dr. A. Berg with geological school-collections, and Prof. Bock with the care and appreciation of what is beautiful and instructive in open nature. The result of this collaboration is a very remarkable and valuable book which ought to be utilised by those teachers of natural science who wish to make their instruction more effective. Where we have been able to test the work, we have found it to be altogether to the point—detailed, precise, and up to date.

(11) Drs. B. Schmid and C. Thesing have made a brave attempt to combine a Who's Who in Biology, a directory of institutes, gardens, and technicians, an obituary, a list of the most important recent biological publications, and a number of short essays dealing with present-day problems. It is the first issue, and we sympathise with the editorial appeal for suggestions rather than criticisms. We would suggest that the editors should re-cast their net. A list of contemporary biologists which omits Bateson, Delage, Wilson (to take an instance from each of three countries), obviously requires revision, and the same remark applies to the pages devoted to the almost impossible task of giving a list of the most important publications. The bibliographies of the works of not a few of the biologists are much in need of pruning: others, such as Sir Ray Lankester's, are as much in need of being brought nearer completeness. The introductory essays on bird-marking, symbiosis, phenology, natural science in schools, problems of modern zoology, microscopic technique, and the like are admirable. As the calendar makes for co-ordination, we wish it success.

THE TOTAL SOLAR ECLIPSE OF AUGUST 21, 1914.

(1) THE ROYAL OBSERVATORY ECLIPSE EXPEDITION TO MINSK, RUSSIA.

THE programme of observations of the Royal Observatory Eclipse Expedition to Minsk, Russia, was in the main the same as that planned for the Brazilian eclipse in 1912, but which rain had prevented from being carried out. The instruments comprised: (1) the Thompson coronagraph, consisting of a lens of 9 in. aperture and of 8 ft. 6 in. focal length, in conjunction with a Dallmeyer negative enlarger, giving an equivalent focal length of 36 ft., for the purpose of taking large-scale photographs of the corona, on a scale of 4 in. to the sun's diameter. (2) Two telescopes of 6 in. aperture, and of focal lengths 2 ft. 3 in., and 6 ft. 6 in. respectively, used in conjunction with green colour filters (Wratten and Wainwright's mercury monochromat), which let through a band in the green in the region of the coronium line λ 5303, the object of these being to obtain evidence as to the presence and distribution of coronium in the corona. In order to disperse such continuous light from the corona as the filter transmitted, a prism was placed before each object glass. (3) The Hills' quartz spectrograph for obtaining the ultra-violet spectrum of the flash and of the corona. For (1) and (2) 16 in. cœlostats were used, and for (3) a cœlostat with a 9-in. speculum mirror, in combination with a speculum condensing mirror. Provision was also made for obtaining iron arc

and solar comparison spectra, for the accurate determination of the wave-lengths.

The expedition was fortunate in having an unobscured view of the eclipse during the whole period of totality, there being much cloud in the sky at the time, and the returning crescent being hidden immediately afterwards. In the town of Minsk, three miles away, practically nothing was seen of totality. Thus the whole programme of observations was carried through.

FIG. 1.—Corona, 2–4 sec., Ilford Process Plate.

To the eye, the corona appeared bright and of a steely-blue whiteness, and during totality the darkness was not very intense. Regulus could be seen shining through the corona, and Mercury and Venus were also visible. The corona was of the intermediate type, with four streamers, and resembling somewhat the 1898 corona. A sheet was spread for the observation of shadow bands, but none were observed. The temperature readings taken during the eclipse show that the shade temperature fell 5·5° F., but the humidity was not affected.

With the coronagraph seven photographs were taken, with exposures varying from 2 to 25 secs., on Ilford Process, Empress, and Special Rapid plates. These show a large prominence on the limb of the sun near the point of second contact, about one-twentieth of the sun's diameter in height. In the neighbourhood of this prominence the corona shows some interesting detail in the form of coronal arches. There was also a smaller prominence on the other limb of the sun. The shape and structure of the present corona is interesting as compared with the records of past coronas, inasmuch as it is of a type which has not been previously studied, viz., that belonging to the sun when near minimum, but with an increasing spot-activity. Fig. 1 shows the corona, near the commencement of totality, photographed on a Process plate with an exposure of 2 seconds, and developed with pyro-soda. Fig. 2 shows it near the end of totality, the exposure being 5 seconds on an Empress plate, developed with methol-quinol.

With each of the telescopes with the colour filters four exposures were made, of 25, 40, 40, and 25 secs. respectively, the refracting edges of the prisms being vertical for the first two and horizontal for the second two exposures. For the purpose of changing from one position to the other, the telescopes had been mounted so that their axes could move upon the surface of a right circular cone the axis of which was in the direction of the beam reflected from the cœlostat. The presence of coronium in the corona should be indicated on the photographs by a sharp ring superposed upon a fainter background due to the dispersed continuous light. The photographs taken enable us to assert that any results obtained without the use of prisms would have been of no value and liable to misinterpretation. Beyond that their evidence is negative. No trace of coronium light is apparent, and, in the absence of other evidence, it must be concluded that coronium as indicated by the green line was almost entirely absent from the present corona.

The photographs taken with the spectrograph are good, though not quite so successful as had been hoped for. More cannot be said about these until they have been carefully measured.

FIG. 2.—Corona, 112–117 sec., Ilford Empress Plate.

H. S. JONES.
C. R. DAVIDSON.

(2) THE AMHERST ECLIPSE EXPEDITION TO RUSSIA.

Although the Imperial Academy of Science at the instance of Dr. Backlund, together with the Government railways, had offered every facility in transportation of observers and instruments, the necessity of immediate mobilisation had made it impossible to deliver my cases in Kieff at the expected time. Many days of patient waiting there had convinced me that it was best to prepare if possible an entirely new set. With the help of Mr. Day, a 6 in. Dallmeyer portrait lens was found in a photographer's *atelier* in the Krestchatik; at the University shop, Prof. De Metz had a long tube and shutter made, which, with a new Dresden camera and plate-holders, provided an adequate outfit—everything except clockwork motion. It was necessary, therefore, to use the tube as a stationary camera, and plates as sensitive as possible so that the diurnal motion should not blur the coronal filaments. Fortunately we put the apparatus together in time and in working order at Kieff, and with the help of Prof. Sleusarefsky found the exact focus, so that little remained to do at the station but set the camera rigidly in exact alignment towards the sun at mid-totality and make the necessary practice drill.

FIG. 1. Prof. David Todd with the camera contrived for the photography of the solar corona during the eclipse on August 21, 1914.

By invitation of Count Bobrinsky, whose estates are in Smala, about 100 miles south-east of Kieff, I was several days his guest, and had abundant opportunity, while enjoying the hospitality also of Prince Trubetskoy, to mount the camera very satisfactorily. The illustration (Fig. 1) shows the instrument in position on the portico of Count Bobrinsky's residence.

Smala proved to be exactly in the line of central eclipse, and certainly no one could have had a better position than in the midst of this superb estate. During totality the sky was shrouded in thinner clouds than elsewhere in Central Russia; so that of the six exposures on Moscow plates, from a half-second to two seconds in length, four of them turned out better than I had expected from the drifting clouds which had in no instance permitted the corona to be seen entire. Two of the four will afford detailed estimates of the light of the inner corona. Star-trails on the plates were made by α Ophiuchi on two nights after the eclipse. As the camera had remained unmoved since totality, the direction of the "parallel" gives exact location of the prominences and coronal details. Both corona and star trail were, of course, developed together on the same plate.

I have pleasure in acknowledging much assistance from Mr. Gubtschefsky, president of the Society of Photographers in Kieff.

DAVID TODD.

THE BRITISH ASSOCIATION IN AUSTRALIA.

MANY of those who made up the "Overseas Party" of the British Association at the recent Australian meeting have now returned home. In a former article it has been stated that some members found it necessary, after the Orient liner *Orvieto* was requisitioned by the Commonwealth Government, to return a week earlier by the P. and O. vessel *Malwa,* which they were only able to catch at Adelaide by leaving Sydney the day before the conclusion of the meeting there; the number of those who did this was twenty-six. The steamer *Demosthenes,* leaving Australia earlier still, *viâ* South Africa, carried a few members. The following P. and O. ship, the *Morea,* a fortnight later than the *Malwa,* carried a party of more than sixty, who were in England by October 16 after a voyage favoured by beautiful weather—as, it may be added, the meeting had been.

Some forty members proceeded northward from Brisbane after the conclusion of the meeting by the Burns, Philp steamer *Montoro* for Singapore; she was reported to have arrived there safely on September 26, so that her passengers may now be nearing home. Of a number who left from Sydney to follow the Trans-American route, some are home already. Others, however, intended to visit New Zealand, in spite of the cancellation of the arrangements which had been made in that Dominion to hold a scientific meeting there. Those who had it in mind to make a stay in New Zealand if possible, either immediately after the Australian meeting or later, numbered not fewer than fifty. The official excursion to Tasmania after the meeting attracted a dozen members or more. A large number whose plans were unaffected by the European situation were carrying out their programmes for a prolonged stay in Australia or elsewhere. The next P. and O.

ship, the *Maloja*, which is due about October 30, should bring a party.

In justice to the Australian Commonwealth and States and the official and unofficial hosts in Australia, to whom the visiting members of the British Association are so deeply indebted, it cannot be stated too clearly that the European crisis was allowed in no way to diminish, if it did not actually increase, the warmth of the reception accorded to the party, and that it did not affect the scientific work of the meeting adversely; in fact, its direct effects were scarcely perceptible in any centre. Immediately on landing at Adelaide, at the beginning of the meeting, a number of members of the Council met the principal representatives of the local organisation in order to assure them that the party would readily fall in with any modification of the programme which might be found necessary, but the question had already been carefully considered, and the answer was at once returned that local opinion was unanimous that the scientific work of the meeting should proceed, even though some slight changes might be found desirable in respect of excursions and social functions. Any such changes proved, in the event, to be negligible. A practical demonstration, however, of the visiting members' profound sense of gratitude to Australia was given when the party subscribed the sum of 611*l*. 6*s*. to the patriotic funds being raised there; this subscription was transmitted at the close of the meeting to the Governor-General, and by him divided equally between the funds in the various States.

If the immediate scientific importance of the meeting has been in some measure obscured, it is confidently felt by all concerned that its good effects will be great and lasting, and that they will become apparent in many directions. While it was inevitable that far less news of the meeting than usual should appear in the daily Press at home, the Australian newspapers reported the meetings more fully than could have been expected in the circumstances. Public interest was maintained to the end; sufficient evidence of that is found in the very large number of local members, and it was interesting to observe how, after the daily enrolment of these members had fallen off abruptly on the declaration of war, it recovered and proceeded briskly, after a few days, up to the beginning of the meetings at Melbourne and Sydney.

The organisation of the meeting could scarcely fail to be of profound interest to those who shared in it. Its ramifications were very wide; it involved, for example, negotiations more or less detailed with various departments of seven Governments (those of the Commonwealth and the States), with a dozen transport companies, and with many other public bodies. The work extended over four years, and was continuous both at home and in Australia for a full year before the meeting began. Upwards of a hundred persons were concerned more or less actively in responsible departments of the organisation; the majority of them were, of course, in Australia, and the officers of the Association at home met with nothing but goodwill at the hands of all these willing collaborators, who have the satisfaction of knowing that the mechanism which they called into being worked splendidly, and possessed driving power sufficient to overcome the resistance set up by the unexpected circumstances in which the meeting took place.

Subjoined is a list of the Research Committees, etc., receiving grants of money, and the name of the chairman of each, appointed on behalf of the General Committee at the Australian meeting:—

Section A—Mathematics and Physics.

Seismological observations—Prof. H. H. Turner ...	£60 0 0	
For printing in connection with above	70 0 0	
Investigation of the upper atmosphere—Dr. W. N. Shaw	25 0 0	
Annual tables of constants and numerical data, chemical, physical, and technological—Sir W. Ramsay	40 0 0	
Calculation of mathematical tables—Prof. M. J. M. Hill	30 0 0	
		£225 0 0

Section B—Chemistry.

The study of hydro-aromatic substances—Prof. W. H. Perkin	15 0 0	
Dynamic isomerism—Prof. H. E. Armstrong	40 0 0	
The transformation of aromatic nitroamines and allied substances, and its relation to substitution in benzene derivatives—Prof. F. S. Kipping	20 0 0	
The study of plant enzymes, particularly with relation to oxidation—Mr. A. D. Hall	30 0 0	
Correlation of crystalline form with molecular structure—Prof. W. J. Pope	25 0 0	
Study of solubility phenomena—Prof. H. E. Armstrong...	10 0 0	
Chemical investigation of natural plant products of Victoria—Prof. Orme Masson	50 0 0	
The influence of weather conditions upon the amounts of nitrogen acids in the rainfall and the atmosphere—Prof. Orme Masson ...	40 0 0	
Research on non-aromatic diazonium salts—Dr. F. D. Chattaway	10 0 0	
		£240 0 0

Section C—Geology.

To investigate the erratic blocks of the British Isles, and to take measures for their preservation — Mr. R. H. Tiddeman	5 0 0
To consider the preparation of a list of characteristic fossils—Prof. P. F. Kendall	10 0 0

The Old Red Sandstone Rocks of Kiltorcan, Ireland—Prof. Grenville Cole	10	0	0			
Fauna and flora of the Trias of the western midlands—Mr. G. Barrow	10	0	0			
To excavate critical sections in the Lower Palæozoic rocks of England and Wales—Prof. W. W. Watts ...	15	0	0			
				£50	0	0

Section D—Zoology.

To investigate the biological problems incidental to the Belmullet Whaling Station—Dr. A. E. Shipley ...	45	0	0			
Nomenclator animalium genera et subgenera—Dr. Chalmers Mitchell	25	0	0			
An investigation of the biology of the Abrilhos Islands and the north-west coast of Australia (north of Shark's Bay to Broome), with particular reference to the marine fauna—Prof. W. A. Herdman	40	0	0			
To obtain, as nearly as possible, a representative collection of marsupials for work upon (*a*) the reproductive apparatus and development, (*b*) the brain—Prof. A. Dendy	100	0	0			
				£210	0	0

Section E—Geography.

To investigate the conditions determining the selection of sites and names for towns, with special reference to Australia—Sir C. P. Lucas	20	0	0			
The hydrographical survey of Stor Fjord, Spitsbergen, by Dr. W. S. Bruce—Mr. G. G. Chisholm	50	0	0			
To aid in the preparation of a bathymetrical chart of the Southern Ocean between Australia and Antarctica—Prof. T. W. Edgeworth David	100	0	0			
				£170	0	0

Section F—Economic Science and Statistics.

The question of fatigue from the economic point of view, if possible in co-operation with Section I, Sub-section of Psychology—Prof. Muirhead	30	0	0			
				£30	0	0

Section G—Engineering.

The investigation of gaseous explosions, with special reference to temperature—(chairman not appointed), vice-chairman, Dr. Dugald Clark	50	0	0			
To report on certain of the more complex stress distributions in engineering materials—Prof. J. Perry ...	50	0	0			
				£100	0	0

Section H—Anthropology.

To investigate the lake villages in the neighbourhood of Glastonbury in connection with a committee of the Somerset Archæological and Natural History Society—Prof. Boyd Dawkins ...	20	0	0			
To conduct explorations with the object of ascertaining the age of stone circles—Sir C. H. Read	20	0	0			
To investigate the physical characters of the ancient Egyptians—Prof. G. Elliot Smith	34	16	6			
To conduct anthropometric investigations in the Island of Cyprus—Prof. J. L. Myres	50	0	0			
To excavate a Palæolithic site in Jersey—Dr. R. R. Marett	50	0	0			
To conduct archæological investigation in Malta—Prof. J. L. Myres	10	0	0			
To prepare and publish Miss Byrne's gazetteer and map of the native tribes of Australia—Prof. Baldwin Spencer	20	0	0			
				£204	16	6

Section I—Physiology.

The ductless glands—Sir E. A. Schäfer	35	0	0			
To acquire further knowledge, clinical and experimental, concerning anæsthetics—general and local—with special reference to deaths by or during anæsthesia, and their possible diminution—Dr. A. D. Waller ...	20	0	0			
Electromotive phenomena in plants—Dr. A. D. Waller ...	20	0	0			
To investigate the physiological and psychological factors in the production of miners' nystagmus—Prof. J. H. Muirhead	20	0	0			
The significance of the electromotive phenomena of the heart—Prof. W. D. Halliburton	20	0	0			
Metabolism of phosphates—Prof. W. A. Osborne ...	20	0	0			
				£135	0	0

Section K—Botany.

The structure of fossil plants—Prof. F. W. Oliver ...	15	0	0
Experimental studies in the physiology of heredity—Prof. F. F. Blackman ...	45	0	0
The renting of Cinchona Botanic Station in Jamaica—Prof. F. O. Bower ...	25	0	0
To carry out a research on the influence of varying percentages of oxygen and of various atmospheric pressures upon geotropic and heliotropic irritability and curvature—Prof. F. O. Bower	50	0	0

The collection and investigation of material of Australian Cycadaceæ, especially Bowenia from Queensland and Macrozamnia from West Australia—Prof. A. A. Lawson 25 0 0

To cut sections of Australian fossil plants, with especial reference to a specimen of Zygopteris from Simpson's Station, Barraba, N.S.W. —Prof. Lang 25 0 0

£185 0 0

Section L—Educational Science.

To inquire into and report upon the methods and results of research into the mental and physical factors involved in education—Dr. C. S. Myers 30 0 0

The influence of school books upon eyesight—Dr. G. A. Auden 5 0 0

To inquire into and report on the number, distribution and respective values of scholarships, exhibitions and bursaries held by university students during their undergraduate course, and on funds private and open available for their augmentation—Sir Henry Miers ... 5 0 0

To examine, inquire into, and report on the character, work, and maintenance of museums, with a view to their organisation and development as institutions for education and research; and especially to inquire into the requirements of schools —Prof. J. A. Green ... 20 0 0

£60 0 0

Corresponding Societies.

Corresponding Societies Committee for the preparation of their report—Mr. W. Whitaker 25 0 0

£25 0 0

Total £1634 16 6

The following research committees, not receiving grants of money, except in a few cases from the Caird Fund, were also appointed:—

Radio-telegraphic investigation—Sir Oliver Lodge.

To aid the work of establishing a solar observatory in Australia—(chairman not appointed).

Determination of gravity at sea—Prof. A. E. Love.

Research on the utilisation of brown coal bye-products—Prof. Orme Masson.

To report on the botanical and chemical characters of the Eucalypts and their correlation—Prof. H. E. Armstrong.

The collection, preservation, and systematic registration of photographs of geological interest—Prof. J. Geikie.

To consider the preparation of a list of stratigraphical names, used in the British Isles, in connection with the lexicon of stratigraphical names in course of preparation by the International Geological Congress—Dr. J. E. Marr.

To consider the nomenclature of the Carboniferous, Permo-Carboniferous, and Permian rocks of the southern hemisphere—Prof. T. W. Edgeworth David.

To aid competent investigators selected by the committee to carry on definite pieces of work at the Zoological Station at Naples—Mr. E. S. Goodrich.

To investigate the feeding habits of British birds by a study of the contents of the crops and gizzards of both adults and nestlings, and by collation of observational evidence, with the object of obtaining precise knowledge as to the economic status of many of our commoner birds affecting rural science—Dr. A. E. Shipley.

To defray expenses connected with work on the inheritance and development of secondary sexual characters in birds—Prof. G. C. Bourne.

To summon meetings in London or elsewhere for the consideration of matters affecting the interests of zoology or zoologists, and to obtain by correspondence the opinion of zoologists on matters of a similar kind, with power to raise by subscription from each zoologist a sum of money for defraying current expenses of the organisation—Sir E. Ray Lankester.

To nominate competent naturalists to perform definite pieces of work at the Marine Laboratory, Plymouth—Prof. A. Dendy.

To formulate a definite system on which collectors should record their captures—Prof. J. W. H. Trail.

A natural history survey of the Isle of man—Prof. W. A. Herdman.

To provide assistance for Major G. E. H. Barrett-Hamilton's Expedition to South Georgia to investigate the position of the Antarctic whaling industry—Dr. S. F. Harmer.

To inquire into the choice and style of atlas, textual, and wall maps for school and university use—Prof. J. L. Myres.

To consider and report on the standardisation of impact tests—Prof. W. H. Warren.

The collection, preservation, and systematic registration of photographs of anthropological interest—Sir C. H. Read.

To conduct archæological and ethnological researches in Crete—Mr. D. G. Hogarth.

To report on the present state of knowledge of the prehistoric civilisation of the western Mediterranean with a view to future research—Prof. W. Ridgeway.

To conduct excavations in Easter Island—Dr. A. C. Haddon.

To report on Palæolithic sites in the west of England—Prof. Boyd Dawkins.

The teaching of anthropology—Sir Richard Temple.

To excavate early sites in Macedonia—Prof. W. Ridgeway.

To report on the distribution of Bronze-age implements—Prof. J. L. Myres.

To investigate and ascertain the distribution of artificial islands in the lochs of the Highlands of Scotland—Prof. Boyd Dawkins.

To co-operate with local committees in excavations on Roman sites in Britain—Prof. W. Ridgeway.

The dissociation of oxy-hæmoglobin at high altitudes—Prof. E. H. Starling.

Colour vision and colour blindness—Prof. E. H. Starling.

Calorimetric observations on man in health and in febrile conditions—Prof. J. S. Macdonald.

Further researches on the structure and function of the mammalian heart—Prof. C. S. Sherrington.

The binocular combination of kinematograph pictures of different meaning, and its relation to the binocular combination of simpler perceptions—Dr. C. S. Myers.

To consider and report on the advisability and the

best means of securing definite areas for the preservation of types of British vegetation—Prof. F. E. Weiss.

The investigation of the vegetation of Ditcham Park, Hampshire—Mr. A. G. Tansley.

To take notice of, and report upon changes in, regulations—whether legislative, administrative, or made by local authorities—affecting secondary and higher education—Prof. H. E. Armstrong.

The aims and limits of examinations—Prof. M. E. Sadler.

NOTES.

DR. A. SMITH WOODWARD will exhibit the new model of the Piltdown skull at the conversazione of the Geologists' Association, to be held on November 6 at University College.

A DESTRUCTIVE earthquake occurred in Asia Minor on October 3, of which brief reports were published shortly afterwards. Fuller accounts have now arrived by letter. The epicentre was in the neighbourhood of Burdur and Isbarta, the chief manufacturing towns of the district. It is stated that both these towns, which lie about 165 and 185 miles east-south-east of Smyrna, are completely ruined. The line of the Ottoman railway from Smyrna to Aidin was damaged, but less seriously than was at first supposed, for through running was resumed in less than twenty-four hours.

THE Paris correspondent of the *Morning Post* says that a committee of representatives of leading learned societies has been formed in Paris to consider the position of German and Austrian men of science and letters who have been admitted fellows of these societies in France. Since the beginning of the war there has been a movement in favour of the removal of all such fellows from the ranks of the societies to which they have been admitted in recognition of the value of the original work done by them, and on October 19 the Académie des Sciences held a meeting *in camerâ* to consider its position in the matter.

AMONG the results of the war will be noticed the obliteration of a large part of the usual weather information over land and sea. In the meteorological charts of the North Atlantic Ocean for November, issued by the Meteorological Office, this is particularly noticeable, and the U.S. Weather Bureau has pointed out that its useful charts of the northern hemisphere have had to be discontinued temporarily. The chart for November above referred to states that under normal conditions the North Atlantic is free from fog in that month, with the exception of a narrow zone between Cape Cod (Providence, U.S.), and Ushant, but that even in the fog zone the frequency is not more than 5, as compared with 40 per cent. in July.

AT the annual meeting of the Royal Society of Edinburgh, held on October 26, the following officers were elected:—*President,* Prof. J. Geikie; *Vice-Presidents,* Prof. T. Hudson Beare, Prof. F. O. Bower, Sir Thomas R. Fraser, Dr. B. N. Peach, Prof. Sir E. A. Schäfer, and Right Hon. Sir J. H. A. Macdonald; *General Secretary,* Dr. C. G. Knott; *Secretaries to Ordinary Meetings,* Dr. R. Kidston, Prof. Arthur Robinson; *Treasurer,* Mr. J. Currie; *Curator of Library and Museum,* Dr. J. S. Black; *Ordinary Members of Council,* Dr. J. G. Gray, Prof. R. A. Sampson, Prof. D'Arcy W. Thompson, Prof. E. T. Whittaker, Principal A. P. Laurie, Prof. J. Graham Kerr, Dr. L. Dobbin, Dr. E. M. Wedderburn, Dr. W. B. Blaikie, Dr. J. Horne, Dr. R. S. MacDougall, and Dr. W. A. Tait.

THE exhibition at the Royal Photographic Society's house (35 Russell Square) of Mr. Lewis Balfour's photographs of "Bird Life on the Bass Rock," is well worthy of a visit by all those who are interested in either the birds or the photography of birds. We believe that Mr. Balfour's special aim in the work was to illustrate the life-history of the gannet. After general views of the rookeries on the rock there follow on a large scale some pairs of gannets on nests, and a series of the young bird chipping its way out of the shell until it is fully hatched out. The growth and progress of the bird is shown almost day by day up to the fourteenth day, and then at frequent intervals up to the twelfth week, when it is ready for flight. Immature birds of their second, third, fourth, and fifth year's growth are shown with adults, and in various attitudes, such as enraged, fighting, carrying sea-weed, flying, arriving at the nest, and so on. These constitute about three-quarters of the whole number of the photographs, the remainder being similar but smaller series, showing black-backed, herring, and kittiwake gulls, guillemots, and puffins. The photography is almost uniformly excellent, the details of the birds showing crisp and clear. The exhibition closes on November 28.

IN addition to the awards announced in April for papers read at meetings of the Institution of Civil Engineers, the council has made the following awards for papers published in the Proceedings without discussion during the session 1913–14:—A Telford gold medal to Mr. J. V. Davies (New York); Telford premiums to Messrs. W. C. Popplewell (Manchester), A. J. Knowles (Cairo), H. Gaskell, jun. (Widnes), P. Rothera (Trichinopoly); the Crampton prize to Mr. H. F. Carew-Gibson (London); and the Manby premium to Mr. W. M. Griffith (Bareilly, India). The Webb prize for the best paper on railway machinery published during the past three years has been awarded to Mr. Henry Fowler (Derby), and the Indian premium for 1914 to Mr. P. Rothera (Trichinopoly). The council has made the following awards in respect of students' papers read during the session 1913–14:—The "James Forrest" medal and a Miller prize to Mr. J. E. Swindlehurst (Birmingham); and Miller prizes to Messrs. T. C. Grisenthwaite (Glasgow), H. J. C. Harper (Bristol), W. P. Nevett (Birmingham), J. M. L. Bogle (Manchester), E. A. Cross (Birmingham), S. Brassey-Edwards (Manchester), G. T. Cotterell (Bristol), D. D. Stanier (Newcastle), W. E. Gurry (London), H. Taylor (Birmingham), and R. C. Rattray (Manchester).

IN *Man* for October, 1914, Mr. A. L. Lewis discusses the standing stones and stone circles of Yorkshire. No dolmens or large non-sepulchral circles seem to be found in the county, but there are numerous

so-called "barrow circles," that is, small circles of stones surrounding tumuli. Many of these have been destroyed, and it is difficult to find those which survive amid the heather of the moors. On the other hand, Yorkshire possesses some very remarkable menhirs, or standing stones, which may be said to form a class by themselves. The longest standing stone in the British Isles is that in the churchyard at Rudstone, near Bridlington, which, so far as excavations have been made, is 40 ft. in height. It faces the line of May-day summer or thereabouts, and it is a mass of coarse ragstone or millstone grit, the place of origin of which is uncertain.

In the *Philippine Journal of Science* for April Mr. E. B. Christie discusses the question of irrigation in Ilocos Norte province. It is carried out by a system of co-operative societies, and the procedure at the digging of a canal is a curious blend of Christian and pagan observances. Most of these societies are under the patronage of a saint, and they hold an annual festival at the conclusion of the harvest season. A mass is sung before the ceremony, and food and drink are laid out for the spirits. When the site for a new canal is selected, a cross is erected. Means are then taken to propitiate the local spirits, presumably because they are supposed to be offended by the disturbance of the soil. Omens are taken to fix a lucky time for the rite. Offerings of a coconut, a chicken, tobacco, and spirituous liquor are laid on an altar. Then an animal, a pig, or an ox is sacrificed near the trench, into which the blood is allowed to drip, with the invocation: "Ditch, this blood is spurted into you in order that the current may be as strong as the current of this blood." The body of the victim is then dragged along the bed of the canal as far as the plot of ground which is to be irrigated. Sometimes a dog is killed and its blood is sprinkled on a plot of ground which is to be levelled to form a rice-field, the dog being eaten afterwards. Animal victims are also said to be buried in the masonry of the canal intakes or gates—a good example of the foundation sacrifice which has been described by Sir E. Tylor.

At the end of the long systematic excavation work conducted by Mr. W. Pengelly in Kent's Cavern, Torquay, there were great quantities of the cave deposits left undisturbed. A little similar work has since been done there which has led to the discovery of other chambers and passages, and the finding of many more of the usual kind of cavern relics. Recently more persistent excavation has been made by Mr. C. Cox, who three years ago went to reside near the cavern. Becoming greatly interested in it and its history, he gives all the time freely spared from his vocational needs to excavating and acting as voluntary guide to the cavern. He has worked out a new passage for some 60 ft., and has obtained numerous fine examples of the cavern products, including well-worked flint palæoliths, jaws, teeth, and other bones in great variety. A week or two ago while moving the earth of the floor of the sloping chamber near the entrance of a channel he intends to excavate, he found a tooth of more than usual interest, having an appearance which suggested human origin. Local medical experience confirmed his conclusion that it is a front tooth of a human being. It is, however, imperfect, being split laterally; the inner portion with the extreme end of the root is missing, so that the specimen is really only the larger outer half of an incisor. Its length is 17 mm., width across the crown, 9 mm., and depth of the enamel face about the same measurement. The enamel edge projects beyond the inner surface, indicating a position in the upper jaw, and permits it being determined as a well-worn left upper human incisor. It may be noted in connection with this find that, occurring in the floor some 3 or 4 in. below the present surface, it would be recorded in the terms used by Pengelly as lying in the fifth-foot level of the cave earth, beneath some two or more feet of granular stalagmite that formed the original floor of the Sloping Chamber.

In the September-October number of *Bird-Lore* Mr. L. A. Fuertes continues the record of his impressions of the notes of tropical birds, dealing in this instance with toucans (illustrated by a coloured plate), cuckoos, trogons, motmots, etc. From their loud and incessant cries, brilliant colouring, and large size, most of the members of the first-named group would, it might be thought, be extremely easy of detection. As a matter of fact, this is far from the case, the explanation, so far as coloration is concerned, being that the brilliant tints of the birds, inclusive of their great uncouth beaks, harmonise closely with those of the tropical vegetation, and the intervening rays of sunlight, amid which they perch.

Nowadays much of the work on mammals by American writers relates to races and so-called species of little or no general interest. An exception occurs in a paper on South American squirrels contributed by Dr. J. A. Allen to the Bull. Amer. Mus. Nat. Hist., vol. xxxiii., pp. 585–597, in which will be found the description of a new generic type (*Notiosciurus rhoadsi*) from the Andes of Ecuador, distinguished from other tree-squirrels by the structure of the hind feet. In those of other species the greater portion of the sole is bare, with the toe-pads separate, and widely sundered from the narrow heel-pad. In the new form, on the other hand, the bare area is restricted to a small patch immediately behind the toes, with the toe-pads crowded together, and the heel-pad, which occupies nearly the whole width of the foot, in close apposition.

The ecology of local fresh-water fishes forms the subject of an interesting illustrated article by Dr. S. A. Forbes, published as a pamphlet by the Illinois State Laboratory of Natural History. Difference in habitat and food forms a basis for grouping fresh-water fishes, although, as the author acknowledges, no hard-and-fast lines of division can be drawn from these. Very noteworthy is the fact that one of the largest American species, the spoon-beaked sturgeon (*Polyodon spathula*), is almost the only one which feeds on plankton when adult, although this constitutes the diet of practically all species in their infantile condition. Some kinds pass directly from this to the permanent food-stage, but in the sheep's-head (*Haplodinotus grunniens*) there is an intermediate in-

sectivorous stage between the infantile plankton-phase and the permanent mollusc-crushing habit.

To the October number of the *Zoologist* Mr. J. C. Moulton, curator of the Sarawak Museum, contributes an account of a collecting expedition in the Sarawak province of Borneo, in which he followed to a great extent the route taken by Dr. Wallace more than half a century ago. In the Sadong district, where the great naturalist often saw three or four in a day, orang-utans are now much scarcer than in Wallace's day, despite the fact that they are protected by Government, except when, as occasionally happens, one of them takes to raiding fruit-trees, when its destruction is permitted. Two photographs of groups of land-Dayaks are of considerable interest. These people—formerly persecuted by head-hunting sea-Dayaks—are the only tribe in Sarawak retaining customs indicative of Hindu influence, due, no doubt, to their Javanese origin.

SOME years ago the Indian Museum published the first part of "An Annotated List of the Asiatic Beetles in the Collection." More recent work, by Mr. H. Gravely, on the Passalidæ—a family nearly related to the Lucanidæ, or stag-beetles—showed that the continuation of a mere list of localities was, in the present state of our knowledge of that group, altogether insufficient, and that illustrated descriptions of all the Oriental species were urgently required. This led to an inquiry into the general principles adopted in the current classification of the family, which was found to require but little modification in order to render it satisfactory from a modern point of view. The result has been a monograph of 176 quarto pages, illustrated with three plates, of the Oriental members of the family, issued as No. 4 of vol. iii. of Memoirs of the Indian Museum. As remarked by the author, the figures of the heads of the various species will be of permanent value, even if some of the systematic portion of the work may require revision.

To the author, Mr. F. Cole, we are indebted for a copy of an article on the history of anatomical museums, reprinted from "A Miscellany: Presented to J. M. Mackay, LL.D." (Liverpool and London, 1914). In discussing the earlier museums, the author points out that these had to depend almost exclusively on desiccation and injection for the display of the anatomy of the soft parts, and that skill in making such preparations attained a development which in certain cases has never afterwards been equalled. Even after the introduction of alcohol as a preservative medium, the use, both of the spirit itself and of the glass vessels in which it is contained, was greatly restricted by their cost, the Hunterian Museum, which, in its founder's time, was unusually rich in moist preparations, having only 4829 of that type, as against 8636 not requiring fluid. The purely anatomical museum attained its zenith with John Hunter, whose collection, in the author's words, had no rivals and no imitators. "Modern ideals discover a narrower outlook, and a relaxing hold on anatomical verity. The museum of the present day is designed to illustrate, first the general principles of classification, and afterwards the elements of systematic anatomy."

THE report of the Refrigeration Research Committee of the Institution of Mechanical Engineers was presented at the meeting of the institution on October 16. With regard to the rating of refrigerating machines, it recommends that the refrigeration be expressed in (kilogram) calories per second, that the standard conditions be, for the cooling water, 15° C., at inlet to 20° C. at outlet, for the cooled material, 0° C. to −5° C., the temperatures being those of steady working; the refrigeration produced under these conditions to be called the "rated capacity" of the machine. The coefficient of actual performance is the ratio of the refrigeration to the work spent in driving, that of ideal performance the ratio of the refrigeration to the work spent in an ideal adiabatic cycle with the same initial and final temperatures and pressures. The quotient of the two performances is to be the "relative efficiency." The report contains entropy-total heat charts for carbonic acid, ammonia, and sulphurous acid, the last two being provisional only. The chairman, Sir A. Ewing, has added an appendix showing the great convenience of the entropy-total heat charts as compared with the entropy-temperature charts in calculations respecting refrigerating machines.

VOL. XI. of the Collected Researches of the National Physical Laboratory consists of reprints of fourteen memoirs by the staff of the institution, which have appeared recently in the Proceedings of scientific societies or in the technical Press, and extend to more than 300 pages. Some idea of the importance of the work carried out at the laboratory may be formed by noting a few of the conclusions to which the authors of these memoirs have arrived in the course of their investigations. Mr. F. E. Smith finds the value of the ohm by his modification of the method of Lorenz slightly less than it has been taken in the past—106·25 instead of 106·30 cm. of mercury. Drs. Harker and Kaye conclude that when a heated metal vaporises it sends out, in addition to the ordinary uncharged metallic particles, electrically charged particles which are shot out at right angles to the metallic surface and produce electric currents of the order of an ampere. Dr. Rosenhain and his staff show that there is a transition point for iron about 900° C., and provide further evidence in support of the theory of the existence of an amorphous cement between the crystals of metallic substances. Mr. Paterson and his colleagues prove that the electrometer must be given a place amongst the instruments suitable for standard measurements in electrical engineering. Dr. Stanton shows how inadequate are the accepted formulæ for the flow of viscous liquids through pipes to represent the actual facts, and Mr. Baker gives the results of his investigation of the effects of the lengths and shapes of bow and stern portions of mercantile ships on the resistance at various speeds. It is to be hoped that the national importance of work of this type will not be overlooked even in such times as the present.

Engineering for October 23 contains an illustrated account of the United States Fleet collier, *Jupiter*, which is of special interest at the present time in view of the importance of the rapid recoaling of war-

ships. The ship is of the twin-screw, single-deck type, and is designed for a speed of 14 knots when at a loaded displacement of 19,230 tons. In addition to having interesting equipment for the handling of coal and oil fuel, the vessel is notable, as the propellers are driven by electric motors, current being supplied to these by turbine-driven generators, the shaft-horse-power available for propulsion being 5500. The total cargo capacity is 966,260 gallons of oil and 9856 tons of coal, or, alternatively, 405,620 gallons of oil and 11,380 tons of coal. The coal handling gear was supplied by the Mead Morrison Manufacturing Company, and the stipulation of the contract was for the delivery of 100 tons per bucket per hour when the gear was operated by winchmen of one week's experience. Owing to the large number of towers supporting the booms and rigging of the coal handling plant, the appearance of the vessel is somewhat unusual.

THE *Scientific American* for October 3 draws a contrast between the ordinary European frontier with its enormous forts and lines of strategic railways, and the Canadian frontier. On the continent of America, the two greatest nations of the world have a common frontier which extends, unbroken, for some 4000 miles. Throughout the whole of this frontier there is not to be found, on either side, a single fortification, or any offensive or defensive military work of any kind whatsoever, and this is the case despite the facts that this far-flung frontier was the eventual outcome of a fierce war, and that these two powerful nations have always been engaged in keen commercial rivalry. That heavily fortified frontiers, backed by military railways, are a menace to a friendly neighbouring State, and provocative of responsive military works, and that they produce an atmosphere of international suspicion and dislike cannot be disputed. There is a growing conviction that the failure of the Teutonic attempt to establish a military dictatorship in Europe will be followed by the final subjugation and control of militarism. Our contemporary can think of no guarantee that would be more effective than the complete obliteration of these fortifications, modern in construction, but essentially medieval in conception, which disfigure European frontiers.

MESSRS. JOHN BARTHOLOMEW AND CO., of the Geographical Institute, Edinburgh, have published a new reduced survey map of north-eastern France, Belgium, and the Rhine. The map is coloured orographically, and is on the scale of sixteen miles to an inch. This scale makes it possible to show with clearness the railways, fortresses, main and secondary roads, and frontier custom-houses. Heights are given both in metres and feet, and the distances between road junctions are marked. The price of the map is 2*s.* on paper, and 3*s.* mounted on cloth.

THE following forthcoming books of scientific interest are announced by *Messrs. G. Bell and Sons, Ltd.* :—X-Rays and Crystal Structure, by Prof. W. H. Bragg; Quantitative Laws in Biological Chemistry, by Prof. Svante Arrhenius; Tuberculosis: a General Account of the Disease, its Treatment, and Prevention, by Dr. A. J. Jex-Blake; Woollen and Worsted Cloth Manufacture, by Prof. R. Beaumont, illustrated; Buddhist Psychology, by Mrs. Rhys Davids. The list of *Messrs. Methuen and Co., Ltd.*, includes:—My Life, by Sir Hiram S. Maxim; On Alpine Heights and British Crags, by G. D. Abraham, illustrated; How to Know the Ferns, by S. L. Bastin, illustrated; British Insects and How to Know Them, by H. Bastin, illustrated; The Mammary Apparatus of the Mammalia in the Light of Protogenesis and Phylogenesis, by Prof. E. Bresslau, illustrated; Mind Cures, by G. Rhodes; and the following first volumes of Methuen's Health Series:—The Eyes of Our Children, by N. B. Harman; Throat and Ear Troubles, by M. Yearsley; The Teeth, by A. T. Pitts; The Care of the body by Dr. F. Cavanagh; The Health of a Woman, by Dr. H. J. F. Simson; Health for the Middle-Aged, by Dr. S. Taylor; The Prevention of the Common Cold, by Dr. O. K. Williamson; and The Hygiene of the Skin, by Dr. G. Pernet.

OUR ASTRONOMICAL COLUMN.

THE ROTATION PERIODS OF TWO OF SATURN'S SATELLITES.—In the Bulletin (No. 64) of the Lowell Observatory Prof. Lowell and Mr. Slipher publish their observations in relation to two of the satellites of Saturn, namely, Mimas and Enceladus, which have led them to deduce that the revolutions and axial rotations of these bodies are synchronous. This investigation on the brilliancy of these satellites was carried out in December, 1913, and the first three months of the present year, and resulted in finding out that these bodies are of very unequal albedo in different parts of their apparent orbits, and the variations recur *in situ* showing that the satellites always turn the same face to their primary. Both the moons appear brightest near their western elongations and faintest near their eastern. Their magnitudes and ranges are given as follows:—Mimas, 12·90 to 13·33; Enceladus, 12·33 to 12·67. Both these bodies are too small to show a disc, so their size has been inferred from their brilliancy relative to Tethys. Two figures accompany the text, in which the observations are plotted diagrammatically.

DIFFERENCE OF LONGITUDE BETWEEN PARIS AND NICE.—In a communication by M. B. Jekhowsky, presented to the Paris Academy of Sciences (*Comptes rendus*, vol. clix., No. 15, October 12) by M. P. Appell, a brief summary is given of the determination of the difference of longitude between Paris and Nice. The astronomical observations have been made at both these stations with the "modèle géodésique de l'astrolabe à prisme," by the eye and ear method, and the chronometric comparisons were made by wireless after the method of MM. A. Claude, G. Ferrié, and L. Driencourt. The chronometer rates were controlled both before and after the astronomical observations by pendulums, and comparisons were made at the beginning and end of each series of observations. The daily wireless time signals from the Eiffel Tower were utilised as a check on Paris and Nice chronometers between the two series of evening observations. The observations were made on the evenings of May 3, 6, 31, and June 5, and the final result of the difference of longitude between Paris and Nice is given as 0h. 19m. 51·204s. ±0·06s.

EFFECT OF HUMIDITY ON PHOTOGRAPHIC PLATES.—It has been previously pointed out that when a photographic plate has been exposed in a telescope for some time the plate gradually loses some of its sensitiveness.

This question is the subject of a short communication to the *Astrophysical Journal*, September, vol. xl., No. 2, by Dr. C. E. Kenneth Mees, of the Kodak Research Laboratory, who, thinking that the cause was due to a change in humidity, made experiments to determine the effect of varied humidity on the sensitiveness and development factor of Seed 23 and Seed 30 plates. Experimenting within a range of 0·5 to 85 per cent. of humidity, and giving the emulsion film time to come into equilibrium with the air, he found that both sensitiveness and development factor decreased about 25 per cent. when the humidity was increased from 0·5 to 85 per cent. This result seems very conclusive, and shows the restraining action of a change of moisture on the sensitiveness of photographic film. Dr. Mees suggests that all photographic materials used for photometric work should be brought previously into equilibrium with the atmosphere in which they are to be used.

Tests of a 24-in. Objective.—At the end of the year 1911 the erection of a 24-in. refractor was completed for the Sproul Observatory, U.S.A. The objective was made by Brashear, the crown disc being furnished by the Parra-Mantois firm of Paris, and the flint disc by Schott and Genossen, of Jena. In 1912 the objective underwent a series of tests at the hands of Profs. John A. Miller and Ross W. Marriott, who used the method of extra-focal images devised by Hartmann. In 1913 a final series of tests was made, and this, with the foregoing, are described by the authors in the October number (vol. clxxviii., No. 4, p. 465) of the Journal of the Franklin Institute. It seems that in the first tests measures of photographs of star images taken through a screen containing circular holes showed certain discrepancies among the focal distances of different parts and zones of the lens, which, while not excessive, were absent before the mounting of the lens. The cause of these discrepancies was traced to a side pressure spring to prevent the objective from sliding in its cell. After a reduction of the pressure further tests were completed with screens containing different numbers of holes. The result was to show that "from every standpoint the lens is an excellent one."

THE RECTORSHIP OF THE UNIVERSITY OF GLASGOW.

The matriculated students of the University of Glasgow, divided into four "nations" under the ancient constitution derived from Bologna and Paris, have unanimously elected M. Raymond Poincaré, President of the French Republic, and member of the academy, to be their rector for a term of three years. For a long time past the recurring elections to the rectorship have been conducted on purely political lines, and the result was always hailed as a party triumph for one side or the other. Mr. Disraeli (1871) was succeeded by Mr. Gladstone (1877), and Mr. Bright (1880); Mr. A. J. Balfour (1890), Mr. J. Chamberlain (1896), Lord Rosebery (1899), Mr. Asquith (1905), and Lord Curzon (1908), were followed by Mr. Birrell (1911).

Before the present national crisis arose, Lord Strathclyde, Mr. Bonar Law, and Mr. R. B. Cunninghame Graham had been selected as their champions by the several political groups. But the students speedily recognised that in the actual situation of the country a party contest was out of place, and the candidates first chosen were withdrawn. The political leaders thereupon, in token of "the close bond of union between France and Great Britain," addressed a joint invitation to M. Poincaré, which the President was pleased to accept. The proposal was received with enthusiasm, and unanimously endorsed by the students. In the absence of any other nomination, the Principal, Sir Donald MacAlister, K.C.B., on behalf of the Senate, at noon on Saturday, October 24, declared M. Poincaré duly elected by the votes of all the "nations."

The rector is the official President of the University Court. He appoints an assessor, who is *ex officio* a member of the governing body. He is "installed," and delivers a rectorial address, at a solemn assembly of the University during the period of his tenure. Otherwise his position is honorary. In the present case the "installation "will have to await the termination of the war.

The names of two relatives of the new rector, Dr. Henri Poincaré and Dr. Boutroux, already appear on the University's roll of honorary graduates. From the beginning of the sixteenth century onwards a Glasgow graduate has from time to time been chosen as rector of the University of Paris. This is the first occasion on which a French scholar has held the rectorship of Glasgow.

THE ROYAL ANTHROPOLOGICAL INSTITUTE.

Prof. Arthur Keith publishes in the Journal of the Royal Anthropological Institute for January–June, 1914, his presidential address on the reconstruction of fossil human skulls. This is, to a large extent, the outcome of the controversy which arose on the reconstruction of the Piltdown skull, in which his scheme differed from that suggested by Dr. Smith Woodward. As a practical test of his methods Prof. Keith invited Dr. Douglas Derry to furnish him with fragments of a specimen skull, which he engaged to reconstruct and to publish the results of his experiment, whatever might be the result. The reconstruction of this skull by Prof. Keith so closely, in his opinion, resembles the cast of the original skull from which the fragments were taken as to confirm the validity of his methods. He is thus led to deny that the architecture of the human skull lies outside the limits of true science. He asserts that it is framed according to definite principles, that all its parts are correlated, and that it is possible from a part—if our knowledge is accurate and full—to reconstruct the whole. The address marks a decided advance in our knowledge of the science of craniometry.

Mr. Henry Balfour contributes to the journal an interesting paper on the art of fire-making with a flexible sawing-thong. This method of fire-production has been traced in three distinct localities: an eastern area extending from Assam to New Guinea; by Miss Mary Kingsley among the Ba-Kele of the Ogowe River in West Africa; and in Sweden, Germany, and Russia, where it is used as a means of procuring need-fire. This strange distribution of the art raises many interesting questions, particularly in relation to the theories of Graebner and his school, who postulate the derivation of these and similar ideas from a single well-defined area, whence they are generally transmitted. In the eastern area it seems to be associated with the Negrito culture, and is possibly a variant of the better known rigid, blade-like fire-saw. In Africa, again, an independent origin is strongly suggested, although the possibility of transmission from the east cannot be quite ignored. In Europe the theory of transmission from the Negritic, Indonesian, pre-Malayan, or Bantu culture can be accepted only with much reservation, and here, too, the inference is that it was independently discovered. Much still remains to be done by examining museum specimens and by the collection

of examples from other parts of the world. Mr. Balfour pleads for assistance in adding to the fine collection of material in his charge in the Pitt-Rivers Museum, Oxford.

The journal also contains an elaborate, well-illustrated paper on the antiquity of man in Ireland as traceable in the older series of flint implements. Needless to say, the character of some of the specimens obtained from the raised beach at Larne and other sites in North Ireland has formed the subject of active controversy, Mr. Knowles asserting that they are human artefacts, while other authorities, as in the case of the eoliths, deny that they are the work of man. In this paper Mr. Knowles urges the validity of his theory with much vigour, and he recognises in some specimens striæ which prove that they belong to the Ice age. He sees in some of them a remnant saved from the precursors of the Chellean and Achulean *coups de poing* of France and the south of England. His arguments deserve serious attention, but it is perhaps too much to say that he will succeed in convincing his opponents.

The institute under its present management has made a decided advance. Its members now number 534—the highest point hitherto attained—as compared with 367 in 1913. During the year it has been engaged in various schemes of research, and has strongly advocated the teaching of anthropology to candidates for the Indian and Colonial Civil Services. But a larger membership is much to be desired, because many important projects, and, in particular, the reorganisation of the library, have been postponed through lack of funds. The present housing of the institute leaves much to be desired, and it is scarcely creditable to the British, Indian, and Colonial Governments and the large number of officials and colonists throughout the Empire that a decided effort has not been made to place this valuable institution on a sounder footing.

PROBLEMS OF THE ANTARCTIC.

One of the most noteworthy meetings during the Australian session of the British Association was the discussion at Sydney on the past and present relations of Antarctica in their biological, geographical, and geological aspects. The four sections of zoology, geology, geography, and botany held a joint meeting for this purpose on August 25, with Prof. A. Dendy in the chair. Sir Douglas Mawson, who had only reached Sydney the day previously from London, was to open the discussion, but he devoted his time more specially to a general account of the work of the Australian Antarctic Expedition. He expressed his belief in the existence of only one land mass in Antarctica. Prof. T. W. Edgeworth David touched on several points. The uneven level of the ice-barrier at its seaward edge could be adequately explained only by its containing beneath its surface flattened-out ribs of glacier ice from the glacier valleys to the south-west and south-east of the barrier. These would account for the inequalities in level of the barrier face, which varies from 20 to 150 ft. above sea-level. In this connection Prof. David pointed out how in the heavily faulted rock strip of South Victoria Land cross faulting had produced low points in the horst through which the inland ice had run. He also dwelt on the importance of the study of Antarctic meteorology in relation to the weather of Australia, and emphasised the value of the Macquarie Island meteorological station.

Mr. Griffith Taylor spoke at some length on glacial erosion. He contended that in 78° S., the latitude in which his observations were made, there is little or no glacial erosion, that it is too cold for it to act, and that the present sculpturing of the land is due to the effects of alternate thawing and freezing. As proof of this theory, he pointed out that the streams flowing from glaciers in summer are clear and not muddy, as, for instance, in the Alps.

Mr. H. T. Ferrar, who was not in entire agreement with Mr. Taylor about erosion, spoke of the tectonics of the continent of Antarctica. He maintained that the evidence showed that the continent had been under a torsional strain. The Pacific side had fallen and caused the Andean fold while the rest stood firm. Mr. Ferrar agreed with Prof. David about the structure of the great ice-barrier.

Prof. A. Penck brought the discussion back to the main problem. He pointed out the oneness of South Victoria Land with Eastern Australia and the absence of folding since Palæozoic times. On the other hand, Graham Land shows a complete divergence from this structure, and a marked similarity to South America, in its folded beds of Tertiary age and marine origin. The great problem is, How are these two regions of Antarctica, so strikingly opposed to one another, joined? It was formerly suggested that the Andean folds were continuous into Edward Land, but this theory found no support in the geological evidence collected by the Amundsen Expedition in that land. Prof. Penck held that the possibility of a strait across Antarctica was not yet disproved.

Dr. R. N. Rudmose Brown agreed that the main problem of Antarctic exploration was to discover the connection between the two divergent structures of Victoria Land and Graham Land. This would be a justification for a long transcontinental journey like that contemplated by Sir Ernest Shackleton. Dr. Brown disagreed with Prof. Penck as to the existence of a strait across Antarctica, and said that the discoveries of Shackleton and Amundsen in the Ross Sea area and those of Bruce and Filchner, as well as the increased probability of the actual existence of Morrell Land, left no room for such a strait. He pointed out that the Deutschland Expedition has not disproved Morrell Land, but that it had, on the other hand, lent colour to its existence.

Capt. J. K. Davis emphasised the importance of deep-sea work around Antarctica, and gave some account of his own explorations and discoveries south of Tasmania in the *Aurora*. He pointed out how little of the coast line of Antarctica was known, and insisted that this important part of Antarctic discovery could be more satisfactorily and easily done from sea than by land journeys. Capt. Davis said he wished to place on record his great indebtedness to Dr. W. S. Bruce for the invaluable help he had given him in deep-sea apparatus and advice in its use.

Mr. F. L. Stillwell spoke of the geological work he had done with the Mawson Expedition, and showed specimens of the rocks obtained. He showed that Adelie and Wilkes Land are of the same plateau structure as Victoria Land.

Dr. G. C. Simpson suggested that an area of five million square miles radiating solar energy into space must have an effect on atmospheric circulation which had not so far been given full importance. Dr. Simpson spoke at length on Antarctic meteorology in Melbourne to Section A.

Other speakers included Prof. A. C. Seward and Mr. C. Hedley, and while the discussion cannot be said to have shed much new light on the main problems of Antarctica, it afforded a useful interchange of views and evoked great interest in Sydney. The time proved all too short for the number of speakers available, who were in consequence almost limited to actual explorers.

R. N. Rudmose Brown.

CLIMATE AS TESTED BY FOSSIL PLANTS.[1]

PROBLEMS connected with the climates of past ages have long exercised the minds of scientific writers, both from the astronomical point of view and from the point of view of the gradual development and distribution of plants and animals, since the earliest periods that have left recognisable records in the earth's crust. My task this evening is to deal with the nature and value of the evidence afforded by plants as to the climates at different periods of the world's history. Even before the study of fossil plants attained the dignity of a science (1706) the opinion was expressed that certain leaves preserved as impressions in Palæozoic strata in Germany bore a closer resemblance to existing tropical genera than to any European forms; and as investigation of the botanical records of the rocks progressed it became increasingly evident that fossil plants often exhibit a close agreement with species characteristic of regions warmer than those where the fossils are found. Plants, it has been said, "are the thermometers of the ages, by which climatic extremes and climate in general through long periods are best measured." It seems a simple matter to draw conclusions as to the climates of former ages from the nature of the vegetation embedded in the rocks; but the more we consider the facts the more fully we recognise the difficulties of interpretation.

At the outset of our inquiry we must endeavour to obtain some general conception of the relation of existing plants to the diverse influences to which they are exposed in order to appreciate their plasticity or power of modifying form and structure in response to the demands of the environment. Plants have generally been preferred to animals as indices of climatic change on account of their inability to escape from uncongenial or injurious conditions unless the change in climate is sufficiently gradual to allow time for migration by the precarious method of travelling afforded by the adaptation of fruits and seeds to dispersal by wind, water, or animal agency. Plants must either become acclimatised or suffer extinction, while animals, unless faced by impassable barriers, can change their home. It is therefore of importance to obtain some general idea of the power of plants to accommodate themselves to changed conditions, and to inquire how far the factors influencing plant-life are able to cause alteration in form or structure and so maintain equilibrium between the organism and its environment. It is well known that closely allied plants can exist under very different conditions, but we are unable to give any satisfactory explanation of this power of adjustment inherent in the constitution of a species. As Prof. Judd reminds me, tropical species in St. Petersburg live through the winter in semi-darkness in glass houses with the roof darkened by a thick covering of matting and snow. The same species is occasionally met with in both temperate and tropical regions: the bracken fern, which monopolises wide stretches of British moorland, grows in tropical Africa, in the Alps and Himalayas, China, the Malay Peninsula, Tasmania, and many other parts of the world where it is exposed to a wide range of climatic conditions. In contrast to this and other cosmopolitan types there are many instances of ferns and flowering plants characterised by a narrowly circumscribed geographical range: some of the genera now confined to a comparatively small area in the tropics are survivals from a remote past when they, or closely allied forms, were widely spread in northern countries. If we take the climatic environment of the surviving species as an index of the conditions under which their predecessors flourished, their presence in European sedimentary rocks points to tropical or subtropical conditions in the Mesozoic era in latitudes now characterised by a temperate or even an Arctic climate. It is, however, very probable that the last strongholds of these ancient and possibly enfeebled types are characterised by climatic conditions less rigorous than those under which their more robust ancestors were able to exist. The "big trees" of California, the genus Araucaria, and the Malayan ferns Dipteris and Matonia afford striking examples of genera now restricted to a small area but formerly very widely distributed. The two surviving species of Sequoia (the redwood and the mammoth tree), now confined to a narrow strip of land bordering the Pacific coast, are the last members of a family that has left many traces of its existence in Tertiary Europe and in other parts of the world. Similarly Araucaria, one of the most venerable of our Conifers, is now confined to Chile and Brazil in the west, and to the eastern part of Australia, New Caledonia, and other Australasian islands, whereas in the Jurassic period species closely allied to the monkey puzzle (*Araucaria imbricata*) and the Norfolk Island "Pine" (*Araucaria excelsa*) flourished in North America, Europe, and other regions north of the equator. A similar history of retreat from northern latitudes to a much more limited tropical home has been deciphered from the remains of Mesozoic ferns that have their modern counterparts in the Malayan genera Matonia and Dipteris.

Though we cannot make any definite statement as to the mode of action of heat on the living protoplasm of a plant, it is possible to formulate some general rules governing response to external factors as illustrated by differences in habit and anatomical characters. The striking contrast in the environment of land and water plants means a considerable difference in the conditions affecting the working of the plant-machine. A species surrounded by water has no need to take measures for the reduction of evaporation or, more accurately expressed, transpiration: the superficial cells require no waterproof covering to prevent loss of moisture from the internal tissues; the water-conducting tissue (or wood) is much less developed in a plant that is not dependent on its roots alone for a supply of raw material. If we cut across the stem of an aquatic flowering plant, *e.g.* the mare's-tail or the water milfoil, we find that the feebly-developed conducting strands are nearer the centre than is the conducting tissue of a land plant. The tensile strain to which the stem is exposed renders desirable a concentration of the strongest tissue, in this case the wood, towards the axial region as compared with the more peripheral disposition of the corresponding tissue in a stem exposed to the bending force of the wind. The stem of the water-plant contains large air-spaces which ensure the provision of an internal atmosphere and an adequate supply of oxygen to the living cells; the support afforded by the surrounding water renders superfluous any special strengthening tissue such as characterises the stems of land-plants in which it is so arranged as to secure maximum efficiency with the least expenditure of material.

Plants growing in dry climates where water is available only at certain seasons, often separated by long intervals of drought, are characterised by structural features correlated with the economising or storing of water. A relatively thick cuticle—an impervious film on the surface of the aerial organs—reduces the loss of water in the form of aqueous vapour from the system of intercellular spaces permeating the internal tissues. The minute pores or stomata regulating gaseous exchange between the plant and the

[1] Lecture delivered before the Royal Meteorological Society on March 18 by Prof. A. C. Seward, F.R.S. Reprinted from the Quarterly Journal of the Society.

external air, and by which aqueous vapour escapes, are often sunk below the level of the epidermis, or the leaves are variously modified in response to the need of reducing evaporation. The formation of water-storing tissue may result in the development of a succulent habit; hard spines replace the flat green leaves, thus by a reduction of exposed thin surfaces effecting a considerable diminution in the amount of water evaporated. In some cases the leaves persist as fleshy storage-reservoirs. Occasionally special cells occur in the leaves of dry-climate plants, in plants the water-supply of which is precarious, which act as small reservoirs to be drawn upon in times of stress. The intercellular spaces that form large cavities in the stems and leaf-stalks of aquatic plants are reduced to the minimum consistent with adequate aeration. Such anatomical features are by no means the monopoly of members of desert floras; they are characteristic of plants growing under conditions in which for various reasons economy in the use of water must be exercised. In salt marshes the water, though abundant enough, contains a relatively high percentage of salt, and this checks absorption by the roots; to avoid the danger of a greater loss of water from the leaves than can be made good by the roots, the plant assumes a habit and anatomical features similar to those characteristic of desert forms. Habitats where water may be plentiful, but to which plants react by acquiring the appearance and structure of species growing in dry regions, have been termed physiologically dry. A salt-marsh plant lives in a physiologically dry habitat; desert plants live in a physically dry locality, and though the environments differ they induce a similar reaction on the part of the two sets of plants. Peat-bogs afford another example of a physiologically dry habitat: the abundance of humic acids in the soil retards water absorption and so reacts on form and structure. In the swampy soil of a fen oxygen is scarce, and the horizontal underground stems of fen-plants tend to avoid the deeper water-logged soil by growing unusually near the surface.

The action of heat and cold is less easy to analyse; the thick covering of bark on the stem of a woody plant is primarily a protection against drought and not against cold. It is rather in the habit of plants than in any specific anatomical features that exposure to cold is reflected. In Russian Lapland it has been shown that it is not the low temperature but the effect of the dry winds that sets a limit to the northward extension of the forests; the young shoots, exposed to the desiccating influence of the air, lose more water than the roots can replace by their enfeebled power of absorption from the cold ground.

The contrast in habit and anatomical structure between individuals of the same species grown at high elevations in the Alps and in the lower meadows is due in part to the action of light and to other factors affecting water-supply. Plants grown before a continuous light under conditions similar to those in high latitudes, afford evidence in their power of response to a changed environment of the remarkable plasticity of vegetative organs; the stems are shorter, the amount of wood and fibrous tissue is reduced, and the cell-walls are thinner than in plants grown under normal conditions. The difference in the intensity of light on the sunny as compared with the shaded side of a tree leaves an impress on the structure of the leaves; a sun-leaf is thicker and is richer in the so-called palisade cells, that is, the cells containing chlorophyll elongated at right angles to the surface of the leaf, than the leaves which grow in diffused light.

The occurrence of the same or closely related species of existing plants under very different climatic conditions is a serious obstacle in the way of employing fossil plants as indices of climate. While it is possible to draw certain general conclusions from the facies of a flora as represented by fossils that can be identified with recent forms, the difficulties are enormously increased when the fossils are extinct types and too distantly connected with living species to afford any safe guide as to the conditions under which they were able to live. It is, for example, certain that in the Tertiary and Cretaceous epochs the vegetation of Arctic regions was such as could not have withstood the low temperature that now characterises Greenland, Spitsbergen, and other ice-covered countries. It is probably safe to assert that in latitude 70° N. in the Cretaceous and the succeeding Tertiary period the temperature was at least as high as that in southern Europe at the present day. This statement is based on the present geographical distribution of recent plants with which the numerous fossils discovered on the west coast of Greenland are most nearly related. It is, of course, impossible to say to what extent the fossil species differed from their surviving relatives in the power of resisting unfavourable conditions, but the fact that many of the Greenland fossils are very closely related to plants now confined to tropical and subtropical countries carries more weight than if the evidence rested on one or two isolated cases. The occurrence in Lower Cretaceous rocks on the west coast of Greenland of fossil ferns very similar to living species of the common tropical genus Gleichenia affords one of several instances of the vicissitudes and changing climates to which groups of plants have been exposed.

The preservation of plants as petrifactions affords valuable data in connection with climatic questions, but it is unfortunately only in comparatively rare instances that the relics of ancient floras retain their tissues in a state that admits of microscopical investigation. In some of the Lancashire and Yorkshire coal seams there are calcareous nodules containing numerous petrified fragments of the stems, leaves, roots, seeds, and spores of plants that flourished in the Carboniferous forests, and by cutting transparent sections of these blocks of stone the tissues can be examined as thoroughly as in thin sections of existing plants. For the most part the trees and smaller plants of the Coal period were converted into coal. A mass of vegetable débris accumulated on the swampy site of a forest, and after submergence and sealing-up under superposed sediments it passed by slow degrees into more or less homogeneous coal. In a few places patches of this peaty material were petrified by the deposition of carbonates of magnesium and calcium derived from mollusc shells and so preserved as samples of the coal-forming vegetable detritus. From thin slices of these patches it has been possible not merely to glean information as to the affinities of Palæozoic plants, but to learn something at least of the conditions under which they lived. It is noteworthy that in addition to the plant-containing nodules embedded in the coal itself, others are found in the roofs of the seams, and in these are occasionally preserved pieces of stems and other organs associated with numerous marine shells. It is probable that while the fragments preserved in the nodules from the seams formed part of the débris accumulated on the actual site of the forest, those from the roof-nodules are waifs and strays drifted by sea-water from the vegetation of higher ground. It has often been stated, though without adequate reason, that the Coal period was characterised by tropical conditions. It is at least certain that the conditions were favourable to luxuriant growth, and it is by no means unlikely that the atmosphere was richer in carbon in the form of carbon dioxide than it is to-day. The flora that has left scanty records in the roof-nodules differs in certain

respects from the richer flora preserved in the coal itself, and the differences are such as lend support to the view that the forests which furnished the coal-producing material grew in swampy ground, while the roof-nodule plants grew on dry land.

Before dealing with the anatomical structure of a few Carboniferous plants further reference may be made to the question of climate. It used to be asserted that in the Coal period the climate was uniform over almost the whole world. In recent years it has been shown that whatever may have been the temperature in the northern hemisphere, there is good reason for believing that in India, South Africa, South America, and Australia the climate was different. During the latter part of the Carboniferous period the vegetation of Europe, North America, and part of China was fairly uniform in composition, and these regions were also characterised by similar physical conditions. The precise correlation of rocks in widely separated localities is often difficult, but it is safe to say that in India and the southern hemisphere strata occur corresponding in geological position with Upper Carboniferous and with Permian rocks in North America, Europe, and China; these southern rocks, conveniently termed Permo-Carboniferous, contain many plants some of which are closely allied to typical northern species, while others are distinct, notably a genus known as Glossopteris, a fern-like plant, though probably a member of an extinct group intermediate in some respects between ferns and seed-plants. From the extraordinary abundance and wide geographical range of Glossopteris in South America, South Africa, India, and Australia, this southern flora is spoken of as the Glossopteris flora; it differs from the contemporaneous northern flora not only in the presence of Glossopteris and several other types unknown in the coal-fields of Europe, but in the absence of many of the most abundant northern plants. With the Glossopteris strata are associated extensive boulder beds, clearly pointing to the existence of glaciers or water-borne ice, and these beds sometimes rest on a platform of solid rock, exhibiting in its rounded outlines and smooth, grooved surfaces unmistakable evidence of moving ice. The conclusions drawn from these and other facts point clearly to the existence of two botanical provinces in the Permo-Carboniferous era, for the most part sharply contrasted, but in a few places intermingling. In the southern hemisphere, and stretching north of the equator into India, was a vast continent, occupying a large portion of what is now the southern ocean, and of this lost continent remnants are preserved in South Africa, South America, and Australia. The abundance of boulder beds and ice-scored rocks in the southern hemisphere demonstrates the prevalence of conditions favourable to the formation of glaciers, a marked contrast to the physical environment of the swamp forests north of the equator.

It is unfortunate that the plants preserved in the southern hemisphere strata are very seldom met with in a petrified state; they occur almost exclusively as casts or impressions. A few specimens of petrified stems recently received from South Africa and India, with others previously described from Australia, afford one piece of evidence bearing on the problem of climatic conditions, namely, the presence of well-defined rings of growth in the wood. Stems from Carboniferous and Permian strata in the northern hemisphere do not as a rule possess any regular rings of growth; their wood is composed of water-conducting tubes of uniform diameter denoting an absence of seasonal changes. A tree growing in a district where a period of inactivity or winter rest is succeeded by a vigorous awakening in the spring, registers the contrast by the production of large vessels in response to the greater demands on the water-supply consequent on the sudden increase of activity in the life of the plant; the production of these water-tubes of wider bore in juxtaposition to the narrower vessels formed in the previous autumn at the close of the growing period gives the appearance of an annual ring. In tropical countries similar annual rings are formed when alternating dry and wet seasons replace spring and autumn, and it occasionally happens that several rings are produced in one year. An extreme case is afforded by a tree of *Theobroma cacao,* the cocoa tree, planted in Ceylon in the summer of 1893, and felled in January, 1901, in which during a period just above seven years twenty-two rings were formed. In this instance the tree shed its leaves three times a year, and each break in the uniformity of its life-processes was marked by the juxtaposition of wide and narrow water-conducting tubes. In many tropical trees and in stems of some plants growing in water there are no annual rings because there are no seasonal disturbances to interfere with the even tenor of existence. As a general rule, however, the rings are annual and afford a fairly accurate measure of age. The occurrence of well-marked rings in the South African and Indian stems of Palæozoic plants is therefore of some interest as an indication of regularly recurring seasons in contrast to the more uniform conditions characteristic of the more or less contemporary northern flora. Petrified stems from Jurassic, Cretaceous, and Tertiary rocks in the northern hemisphere usually show well-defined rings of growth.

An interesting illustration of the employment of the relative breadth of concentric rings of growth in trees as a guide to climate is given in a recent paper by Mr. E. Huntington in a Smithsonian Report for 1912. This author, from observations made in the drier regions of Central Asia and other countries, was led to the conclusion that during the last 3000 years there were periods characterised by a greater amount of moisture, the climatic changes being of a fluctuating kind. He afterwards extended his observations to California, Arizona, and New Mexico, where ruins of prehistoric settlements afforded evidence of less arid conditions than now prevail. Evidence derived from different sources points to the occurrence of three main periods of relative prosperity in both the eastern and western hemispheres. To test this hypothesis an examination was made of the growth-curve of certain forest trees in relation to the rainfall during the last forty years; this showed a close agreement and justified the use of the measurement of rings in trees, reaching in some cases an age of more than 3000 years, as an index of external influences. A curve of growth based on the relative breadth of the rings in several stumps of old Sequoia trees showed marked pulsations which on the whole coincide with climatic changes as deduced from other data

We may next briefly consider the nature of the evidence afforded by anatomical features exhibited by petrified plants from English coal seams. One of the commonest genera in the forests of the Coal period was that known as Calamites, similar in habit to modern Horsetails, but attaining the proportions of a tree with a thick woody stem. The leaves of slender foliage shoots occasionally preserved in the calcareous nodules from the coal are characterised by palisade cells disposed radially and at right angles to the surface, an arrangement correlated with fairly bright illumination rather than dull diffused light. The structural features on the whole suggest a plant living under conditions where the output of water from the leaves was kept within prescribed limits. The roots of Calamites contain large air-spaces in the cortex similar to those in the stems and roots of recent water-

plants. Another common type in the Coal-period forests was Lepidodendron, an arborescent member of a class including the existing club mosses and similar plants, which reached a height of at least 100 ft., and had the power of producing an ever-widening cylinder of wood like that of a pine or an oak. The stem rose from a dichotomously branched subterranean organ that grew to a considerable length in a horizontal position a short distance below the surface of the ground, precisely like the underground organs of plants in the partially water-logged soil of a modern fen. The leaves were well provided with stomatal pores situated in grooves on the under surface, an arrangement suggestive of life under conditions requiring economy in the expenditure of water. Certain anatomical features in the stem suggest that the tree grew in swampy soil or possibly with the lower part of the trunk immersed in water, like the plants in a tide-swept mangrove swamp. A different type of Palæozoic plant is illustrated by Lyginopteris, a remarkable generalised genus with the habit of a slender tree-fern, but agreeing with the higher plants in the possession of true seeds. The stem bore aerial roots characterised by a covering of thin-walled cells, which may have enabled these organs to absorb water from a moist atmosphere. Another extinct genus from the Coal Measures, Sphenophyllum—so called because of its wedge-shaped leaves—affords in its long and slender stem and certain anatomical peculiarities evidence of a climbing habit, and suggests a genial climatic environment. The genus Cordaites, particularly abundant in some of the French coal-fields, and met with also in English localities, resembled in habit, and to some extent anatomically, the Kauri Pine (*Agathis australis*) of New Zealand. The wood is uniform in structure and in specimens from the northern hemisphere without regular rings of growth. The long, flat leaves reveal a distribution of supporting tissue in the form of I-shaped girders as efficient mechanically as the corresponding tissue in leaves of existing plants adapted to resist the force of the wind. Groups of small lateral roots of Cordaites have been found in a petrified condition, containing in their cortex the delicate tubular cells of a fungus, and it is believed that this association of fungus and root affords an example of symbiosis, the two organisms living together to their mutual advantage. It is noteworthy that certain recent trees, such as the Alder, inhabiting swampy ground, are characterised by an association of a fungus with short fleshy roots similar to those of Cordaites, the fungus assisting the roots to absorb water from a soil rich in humic acid. It may be, therefore, that this discovery of symbiotic relationship in the roots of a Coal-period tree supplies additional evidence in favour of a swampy habitat.

Attention may now be directed to the vegetation of a more recent geological period, namely, that known as the Jurassic. Sedimentary rocks of this age are often rich in fossil plants, but as yet the present dominant class, the flowering plants, had not begun to assert itself in the struggle for existence. Jurassic floras are known from the Arctic regions, many parts of North America, Europe, and Asia, from South America, and so far south as Graham Land, also from India, China, Australia, and elsewhere. There is conclusive evidence of the almost world-wide distribution of certain plants during this period of the earth's history, and despite our imperfect knowledge of the floras, we are justified in stating that the available data afford no satisfactory evidence of any well-marked differences in the nature of the vegetation in various latitudes such as might fairly be expected had there been climatic zones comparable with those of the present era. Identical or closely allied species of Jurassic and Cretaceous age are recorded from Greenland, England, India, and Graham Land, and, so far as it is possible to base any conclusions as to climate on a comparison of these extinct plants with modern forms, they indicate an environment characteristic of subtropical or tropical regions. A remarkable example of wide distribution is afforded by some large fronds described from Lower Cretaceous rocks in Greenland by the late Oswald Heer, belonging to a class of seed-plants known as the Cycadales or Cycads, now represented by a few genera for the most part tropical in their distribution; the most northerly members of the class occur in Florida, while the great majority grow in southern countries. Fossil cycadean fronds very similar to those from the west of Greenland are common in the Jurassic plant-beds at Whitby and other localities on the Yorkshire coast, also in strata of the same age in India, Siberia, California, and many other parts of the world. A few years ago members of a Swedish expedition discovered several Jurassic plants in Graham Land (lat. 63° 15′ S.), on the edge of the Antarctic circle, among which were cycadean leaves almost identical with the slightly more recent (Lower Cretaceous) specimens from Greenland. Cycadean plants of Jurassic and Lower Cretaceous age are represented in several parts of Britain, in most cases by impressions of leaves, but sometimes, as in the Isle of Portland, by large stems and occasionally by petrified flowering shoots; the latter have supplied important information as to the affinity of these extinct members of the class, and incidentally their structure points to circumstances necessitating efficient protection against drought

By treating with acid the carbonised film that can often be detached from an impression of a fossil plant preserved in shale, it is sometimes possible to obtain a preparation of the mummified cuticle or superficial covering of a leaf suitable for microscopical examination. Such specimens furnish information as to the structure and number of the stomata, and the data may be of value as criteria of climatic conditions. The carbonised impressions of cycadean fronds from the Jurassic plant-beds of Yorkshire, recently investigated by Mr. Hamshaw Thomas, of Cambridge, furnish particularly good preparations of the resistent cuticle, the only part of the leaf that has escaped destruction, and these supply a clue not only as to systematic position but also with regard to the structure of the mechanism by which the plants regulated their output of water and gaseous exchange with the atmosphere. Although it is rash to institute a close comparison between extinct types and their nearest living representatives as regards climatic conditions, the data obtained by a study of Lower Cretaceous and Jurassic floras throughout the world point to a greater uniformity in the vegetation, and indicate the prevalence of a higher temperature in Arctic and Antarctic regions than at the present day. It has recently been stated by Dr. Gothan, of Berlin, that the comparative study of petrified wood affords evidence of seasonal changes in Arctic lands as opposed to a greater uniformity of conditions—as indicated by the absence of annual rings—in tropical regions; but the data are at present scarcely sufficient to justify any definite pronouncement as to the occurrence of climatic zones during the Jurassic period.

Our knowledge of the more recent geological periods is as yet too meagre to warrant any very precise conclusions as to their climates. The older Tertiary floras are characterised by several flowering plants closely related to modern species in subtropical and tropical countries; fossil seeds from the London clay and from beds of similar age in Belgium and practically identical with those of Nipa, a palm which flourishes in the swampy ground of tropical estuaries. As the buoyant

seeds of Nipa now abound in the waters of the Ganges, the seeds of their Tertiary predecessors floated in the river by which the muddy sediments were deposited that now form the London clay. The subtropical flora of England was gradually modified and partially exterminated as the result of changes in physical conditions which culminated in the Ice age.

It has long been known that in many parts of the British coast there are exposed at low tide stretches of peaty soil containing stumps of forest trees; these submerged forests, or Noah's Woods as they have been locally named, in reference to their supposed connection with the Deluge, point to a higher level of the land subsequent to the Glacial period. It is probable that at the time represented by the oldest submerged forest the whole of the southern part of the North Sea "was an alluvial flat connecting Britain with Holland and Denmark, and to some extent with France."[2] The prevalence of the oak indicates a mild climate: the fauna and flora as preserved in the submerged forests are described by Mr. Clement Reid as poor and monotonous, characteristic of a period of transition between the Ice age and the climatic conditions of modern times. In the alternate succession of old forest-beds and estuarine silts we have an epitome of changing level and fluctuating climates, in part at least during the Neolithic age and extending into the period when man used polished flint implements; the Arctic plants had disappeared, and at a later stage, as the climate improved, more southern species were able to establish themselves on British soil.

The testing of climate by means of fossil plants becomes easier the nearer we approach the present era; the greater the contrast between the floras of the past and those of the present the more hazardous it is to draw conclusions as to temperature. It is from a careful study of the anatomical characters of extinct plants that we are enabled to form opinions, not so much as to temperature, but as to the relation of the plants to water and light as indicated by those structural features which in recent species afford the safest index of external conditions. As our knowledge of recent plants increases and we learn more about the operation of the several factors concerned in the moulding of structure, the better able we shall be to speak with confidence as to the conditions under which they lived and extracted from the atmosphere the carbon from which we now regain the energy originally absorbed as sunlight by the green leaves of Palæozoic plants. As additional facts accumulate with regard to the geographical distribution of the plants of former ages we shall be in a better position to confirm or to modify the conclusions based on the material now available as to the comparative uniformity of climatic conditions in the Jurassic period. Much of the palæobotanist's work necessarily consists in the collection and identification of material preserved in sedimentary rocks, but one of his aims should be to acquire such knowledge of the present relation between plants and their habitats as may enable him to interpret with greater confidence the botanical records of former ages.

[2] "Submerged Forests." Clement Reid.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Lord Kitchener has been elected rector of the University of Edinburgh by the unanimous vote of the students.

Dr. Sydney Chapman, who was elected a fellow of Trinity College, Cambridge, last year, has now been appointed to the staff of the college as lecturer in applied mathematics, and has resigned his position as chief assistant at the Royal Observatory, Greenwich. Mr. John Jackson, Trinity College, Cambridge, has succeeded him at Greenwich.

A copy of the new issue of "The Cambridge Pocket Diary, 1914–15" has been received from the Cambridge University Press. The diary appeals especially to teachers and students in institutions of higher education, because it covers the academic year instead of following the ordinary calendar.

By the will of the late Mr. William Gibson the sum of 10,000*l*. is bequeathed to Queen's College, Belfast, upon trust for investment and to form a "Gibson Scholarship Fund," of which the income is to be applied in the encouragement of education in agriculture by the establishment of Gibson Scholarships for resident undergraduates of the college, being sons of farmers in the counties of Down or Antrim.

The Manchester School of Technology possesses particulars of more than 550 students who were in attendance at the college during the academic year 1913–14 and are now serving in various branches of his Majesty's forces. With a view to the completion of a roll of honour, which shall also include the names of past students engaged upon military service, the registrar will be glad to receive any information from such persons themselves or from their relatives or friends.

The Martell Scholarship in Naval Architecture has been awarded by the council of the Institution of Naval Architects to Mr. F. J. A. Pound, H.M. Dockyard, Portsmouth, who is now proceeding to the Royal Naval College, Greenwich. The scholarship is of the value of 100*l*. per annum, and tenable for three years. The fund which is being raised in connection with the Institution of Naval Architects as a memorial to Sir William White has now reached a total of nearly 3000*l*., and it has been decided to devote the principal part of the fund to the establishment of a scholarship for research work in naval architecture, particulars of which will be announced in due course.

It is announced in *Science* that Baker University, Baldwin, Kan., has completed its 100,000*l*. endowment fund, of which the general education board of New York gave 10,000*l*. The rest was contributed by 10,000 persons, the largest gift from any one of them being 5000*l*. The people of Baldwin, a town of 1200 population, gave 9000*l*. Central College, Fayette, Mo., too, our contemporary says, has completed a campaign to increase the productive endowment of the college by 60,000*l*. Of this amount the general educational board contributed 15,000*l*. This fund increases the endowment of Central College to 100,000*l*. The grounds, buildings, and equipment are valued at 60,000*l*.

An interesting indication of the effect of the war on American universities, says the *Scientific American*, is afforded in a statement given out recently from the chemistry department at Columbia University. According to that department, students who prior to the war had arranged to go to Germany to study now seek information as to the courses afforded in the United States, and it was estimated that when the University opened, the registration at Columbia in all of its departments would be materially increased through the students who cannot pursue their studies abroad. One of the courses which is especially attracting those who had contemplated a winter at the German institutions is that afforded in industrial chemistry.

The following free Chadwick Public Lectures will be delivered in London during the months November, 1914, to January, 1915:—November 14, 21, and

28, "Camp, Ship, and Hospital Hygiene," Dr. A. T. Nankivell; December 4 and 11, "Government and Military Sanitation in the Tropics," Sir Ronald Ross; January 15, 22, and 29, "War and Disease," Dr. F. M. Sandwith. With the sanction of the Medical Director-General of the Navy and by arrangement with the Surgeons-General of the respective ports, a course of three Chadwick Lectures on naval hygiene will be given by Prof. W. J. Simpson, at Portsmouth, on November 27 and December 4 and 11, and at Plymouth on November 28, December 5 and 12. Further particulars of these and other Chadwick Lectures may be obtained from the secretary, at the offices of the Chadwick Trust, 8 Dartmouth Street, Westminster.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 12.—Ed. Perrier in the chair.—H. **Douvillé** and M. **Couyat-Barthoux**: The massif of Moghara, to the east of the Isthmus of Suez.—André **Blondel**: New diagram of alternators with projecting poles.—B. **Jekhowsky**: The determination of the difference of longitude between London and Nice by wireless telegraphy. The radiotelegraphic method described by Claude, Ferrié, and Driencourt was employed. The difference of longitude between Paris and Nice was found to be 0h. 19m. 51·204s. ±0·06s.—E. F. **Gautier**: A Pliocene volcano at Tigri, in eastern Morocco.—Stanislas **Meunier**: The presence of chondria in caillite; consequences for the mode of formation of the meteoric irons.

CAPE TOWN.

Royal Society of South Africa, September 16.—Dr. L. Péringuey, president, in the chair.—A. E. V. **Zealley**: The great dyke of norite of southern Rhodesia: petrology of the Selukwe portion. The well-known great dye of southern Rhodesia extends for some 300 miles throughout the territory, and has a width of outcrop of about four miles. It has usually been regarded as composed of ultra-basic rocks, such as picrite. The author, however, takes the view that it should be termed a dyke of norite.—H. A. **Wager**: The Mosses of South Africa. The author gives a catalogue which he states is the first attempt that has been made of publishing a list of the Mosses already recorded from South Africa, except for a small catalogue of the Mosses of Cape Colony published by J. Shaw in 1878.—T. F. **Dreyer**: A Mesostoma from Bloemfontein (*M. karrooense*, n. sp.). A description is given of this new species of worm obtained from a small temporary pond on clay soil, which is always contaminated with cattle droppings.—Dr. T. **Muir**: Note on Hesse's generalisation of Pascal's theorem. The purely geometrical theorem known as Pascal's was investigated by Cayley and others as a theorem in *co-ordinate* geometry, and Hesse, in doing so, had the good fortune to employ certain identities which he saw to be capable of a wider application, and thus to lead to a generalisation of Pascal's geometrical result. The present paper extends the said identities and seeks to place them in their natural relation to others of importance in a different domain.—H. **Bayon**: Herpetomonidæ found in *Scatophaga hottentota* (Diptera) and *Chamaeleon pumilus* (Lacertilia). Descriptions are given of flagellate protozoa found as parasites in the common "blind-fly" on Robben Island and in the chamæleon. Though slight differences in size and appearance are noticeable in these Herpetomonads from different sources, still they certainly are not more marked than those found in samples taken from the same artificial culture of Leishmania at a few days' interval; therefore it does not seem advisable at the present stage of our knowledge to postulate two distinct species of protozoa. It does not seem excluded that a chamæleon can get infected through swallowing a fly containing Herpetomonidæ in its gut.

DAIRY CHEMISTRY AND DAIRY CONTROL.

Dairy Chemistry: A Practical Handbook for Dairy Chemists and others having Control of Dairies. By H. D. Richmond. Second edition, revised. Pp. xi+434. (London: Charles Griffin and Co., Ltd., 1914.) Price 15*s*. net.

THE first edition of this book has been out of print a good number of years now, and many inquiries must have been made for the new edition of "Richmond." This second edition will therefore be welcomed by a large section of those who are interested in dairying, for the information it gives is difficult to obtain elsewhere.

The main arrangement of the new edition is similar to what it was before, and it would not be easy to improve upon much of the subject-matter. In the first chapter, for example, there is a particularly clear account of the constituents of milk, and sufficient detail of the chemistry of the constituents is given to satisfy any inquirer. Following upon this chapter comes one which deals with the analysis of milk, and here are given in detail the various methods of determining the specific gravity and the formulæ for calculating the total solids, etc. The milk scale is also explained very fully. Attention may here be directed to the author's water oven, which appears to be admirably adapted to the drying of milk samples if a vacuum drying apparatus is not available.

The quantitative methods for the estimation of boric acid and of milk sugar are given, and also the gravimetric and volumetric methods for the estimation of fat. Additional matter in this chapter deals with the acidity of milk and the method employed for indirectly estimating the proteins by means of the aldehyde figure.

The analysis of sour milk is dealt with very fully and also the methods for the examination of milk powders, which are now coming on to the market in increasing quantities. The chapter on the variation in the composition of milk calls for no special remark, except that the paragraph upon the influence of feeding, etc., upon the composition of milk puts very clearly before the reader what is known upon the subject. Those paragraphs that deal with the composition of condensed milk and milk powders will be found very useful for reference. There is also a great deal of useful information contained in the chapter upon the chemical control of the dairy, and by means of it the chemist ought to have no difficulty in checking the milk as it comes into the dairy and ensuring that it leaves, whether as milk or some other product, in a pure, clean form.

The determination of the fat percentage of milk by centrifugal methods (Gerber and Leffman Beam) is gone into very fully, and much practical advice is given.

A dairy chemist must also be something of a bacteriologist, and there is a chapter devoted to this side of his work. The outline of the chief bacteria in connection with milk and the methods of making nutrient media will be found useful. In view of the fact that some authorities place considerable reliance on the reductase and fermentation tests, a little more detail of the manner in which these tests are made would have been helpful. Both these tests can be carried out rapidly, and once the operator has accustomed himself to them and taken due precautions, they serve to give many valuable indications of the cleanliness or contamination of the milk.

The chapter on butter is excellent, all the chief methods of analysis being given in detail. For comparative purposes a brief account of the manufacture of margarine would have been useful. There has not been much alteration in the chapter on cheese and other milk products, but Van Slykes' method for the estimation of products of ripening, which looks as though it would become a standard, is given. The last chapter deals with the calibration of apparatus, and if some of the juniors in every laboratory were set to calibrate the burettes, pipettes, etc., it would be an excellent training and would show how inaccurate much of the cheap glassware is.

GEOLOGICAL BOOKS FROM AMERICA.

(1) *Introductory Geology.* A text-book for Colleges. By T. C. Chamberlin and R. D. Salisbury. Pp. xi+708. (New York: Henry Holt and Co., 1914.) Price 2 dollars.

(2) *Engineering Geology.* By Prof. H. Ries and Prof. T. L. Watson. Pp. xxvi+672. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 17*s*. net.

(1) THIS is essentially an abridged edition of the "College Text-book of Geology," published five years ago, and is perhaps the most readable of the volumes contributed to geological literature by these two distinguished American teachers. In the process of concentration they have avoided a jejune presentation of their subject, the treatment being interesting throughout. A vivid sense of the out-of-doors aspect of geological study is given by a large number of fine illustrations of the operation of geological agencies in different parts of the world.

The first 300 pages are devoted to geological processes and materials. Here are described the

work of the atmosphere, of overground and underground waters, and of snow and ice, vulcanism and the movements of the earth's crust, and the nature and arrangement of rock-types and rock-masses. The second part, of some 400 pages, deals with historical geology. This should be of great service to students, especially those outside America, by providing a generalised, but not too brief account of the stratigraphy of North America, a subject of which no very satisfactory digest has hitherto been available. A classification of geological time into five eras is adopted — archeozoic, proterozoic, paleozoic, mesozoic, and cenozoic—and the description of the first of these is preceded by a discussion of the origin and constitution of the earth on the Laplacian and planetesimal theories respectively.

This part of the book is illustrated by numerous maps, sections, and figures of fossils, most of which are good. But the eighteen full-page maps showing the outcrop, underground extent, and eroded areas of the several systems in America are so largely conjectural that it is a question whether a single geological map in colours showing the actual outcrops, as at present known, would not have been more suitable and useful in a book of this kind. Many of the sections, especially those taken from the publications of the U.S. Geological Survey, seem unnecessarily detailed, and have suffered by reduction: their educational value might have been greater if they had been redrawn in a more diagrammatic form.

The book is an admirable statement of physical and stratigraphical geology from the American point of view, and will doubtless be warmly welcomed and much used by students and general readers for many years to come.

(2) This volume is based upon the courses in geology which the authors have been giving, for some years past, to students of engineering. The scope of the work is wide, and its treatment fuller than in most books on the subject which have hitherto appeared.

Chapters dealing with the minerals of rocks, and with the occurrence and origin of the rocks themselves, are followed by one on tectonics and metamorphism, in which the importance of jointing, cleavage, folding, faulting, and other rock structures in engineering operations are fully dealt with. This is succeeded by a chapter on rock-weathering and the formation of soils. The next two deal with surface and underground waters, and here the geological principles underlying water-supply, drainage, the sinking of wells, the construction of reservoirs, etc., are thoroughly discussed. A short chapter on landslides follows, and then two on the action of waves and currents in seas and lakes, and its bearing upon coastal erosion and harbour construction. The origin and economic uses of glacial deposits are then described. The remaining chapters deal with specific materials of importance to the civil or mining engineer, such as building stone, lime, cement, plaster, clay, fuels, road foundations, and road metals; the last chapter, intended for the metal miner, consists of a short account of the general principles of ore-formation and of the geology of certain of the useful metals. This, from limits of space, is necessarily somewhat inadequate.

At the end of each chapter useful references are given to additional literature on the subject therein dealt with. The book is well illustrated, and there is a triple index referring to subjects, localities, and authors. It is undoubtedly a useful addition to what has already been written on engineering geology. It is eminently practical, and its very direct application to a great variety of engineering problems should commend it, not only to students, but also to engineers in actual practice.

C. G. C.

APPLIED ELECTRICITY.

(1) *Alternating Currents and Alternating Current Machinery.* By Prof. D. C. Jackson and Dr. J. P. Jackson. New edition, rewritten and enlarged. Pp. ix + 968. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 23*s.* net.

(2) *The Elements of Electricity.* By Prof. Wirt Robinson. Second edition. Pp. xv + 596. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 10*s.* 6*d.* net.

(1) IN its thirteen chapters, this work covers fairly thoroughly the ground suggested by its title; in most places the theoretical side is treated with at least sufficient detail, but the constructional side has also received a good share of attention. We should have liked a somewhat fuller discussion of the motor-converter, and think the time is also ripe for some mention of the Kapp and Scherbius phase advancers and of the Hunt Cascade motor. The first few chapters impressed us very favourably, and although we were somewhat disappointed with the later chapters, we consider the book a good one, which will be of service to advanced students.

From the very beginning, the authors use the complex quantity, but it is not until chapter v. that we get a full explanation of the method. This chapter is an excellent one, but should have come earlier. The numerical examples given (single-phase problems) show well the use of the

complex quantity, but are scarcely sufficiently difficult to bring out any advantages for it, as the actual working is exactly the same as would be done by an intelligent student who had never heard of the Steinmetz methods. In a later chapter on polyphase circuits, other examples occur in which algebraic processes have to be carried out before substituting numerical values. In these the advantages become more obvious.

The authors do not quite attain to the standard set in their preface of "avoiding the error of presenting unnecessary formulas." On the contrary, we feel that a formula has been inserted wherever the slightest excuse for it can be found, even when the same formula has been given several times already.

The facts of nature do not depend on a particular choice of units, or, indeed, upon the existence of any units at all. It is therefore quite superfluous to introduce units into the mathematical treatment of these facts. Why will all authors not let their symbols stand for the *thing* itself, instead of for the number of times it contains some particular unit? The length of a foot-rule remains the same whether we call it "one foot," "12 inches," 30·48 . . . centimetres, or 304·8 . . . millimetres. The symbol L can just as well represent the length itself as any of these numbers, and in this way we are freed from the necessity of continually stopping to name the units to be employed, and from the irritating repetition of numbers such as 10^8, $4\pi \div 10$, 60, 746, 33,000, and so forth, which have nothing whatever to do with the laws, but arise from some particular (and unfortunate, although customary) choice of units, and thus distract attention from the real point under discussion. In the book under review, pages and pages might have been saved in this way.

Taking the book as a whole, the explanations are not as clear and concise as they might be; indeed, we found it exceedingly difficult to follow some of them. Several hydraulic analogies are given, but we are very doubtful whether these are really helpful, because the laws of hydro-dynamics have to be strained to make them fit the electrical case, and not infrequently the student's knowledge of that subject is less than of electricity.

(2) Except that part v. goes rather more fully into the technical side than is customary in books with its title, this book covers the well-worn ground of elementary magnetism and electricity. It contains little that is original in matter or in method, and its mathematics is uneven.

Many of the statements given ought to have attached to them the qualifying conditions under which alone they are true. Parts of the book are painfully laboured over some small point, while others are extremely superficial and betray a lack of insight into the true inwardness of the matter discussed.

In our science we have many traditions and dogmas from which we must ultimately break loose, and the sooner this is recognised by the writers of elementary text-books the better it will be for our students. What was best half a century or more ago is not necessarily even good now. Consider the electrostatic and electromagnetic systems of definitions. In chapter 39 the absurdity of the dimensional relations which arise from these definitions is pointed out; but in the other chapters which form the real book, we still have the old Gauss system omitting μ and κ. Why not omit the electrostatic system altogether? The sum total of our loss would be a fund of examination questions and a source of confusion as to what is intended when one of our most prominent physicists tells us that the charge of an electron is so many "units." The dielectric constant (we object to our author's "dielectric capacity") of air or other material would then appear to be what it really is—a thing the value of which has to be determined by experiment like its density, elasticity, or any other property.

Ohm's law, electromotive-force, and potential difference are always stumbling blocks. We should not deliberately blind our students to more than one-half of the phenomena by telling them that the current must flow from high potential to low potential; that a current must be flowing if two parts of a conductor are at different potentials; that a current cannot flow unless there is a potential difference; and that the P.D. is equal to the product of the resistance and current. When restricted to the proper cases, all these statements are quite true; but not a single one of them is always true, and the first and last are not even true in the majority of instances. We have only to consider what takes place in the battery branch of a circuit; in a homopolar dynamo; in a copper ring while a magnet is being thrust symmetrically into it, or in an ordinary electric motor, to see how badly we treat our students when we saturate them with these ideas, which they must later unlearn if they continue the subject.

In this book we have "resistance" in chapter 24, "Ohm's law" in chapter 25, and "Joule's law" in chapter 35. Surely the essential thing about resistance is that it causes a generation of heat when a current flows, and these two laws are merely different ways of looking at the same physical fact. A true understanding of electromotive

force would at once show that this is the case, and that the ultimate result of both laws is that the property of a given conductor which we call its "resistance" is a constant under certain conditions.

Again, we greatly object to the common practice of dragging in Ohm's law in connection with the magnetic circuit. Since the reluctance of the iron parts is not independent of the flux, even the mathematical analogy is very imperfect. There is no *real* analogy at all, for in the magnetic case nothing flows, and there is no continual generation of heat while the flux exists. A comparison with Hooke's law about stress and strain would be much more sensible.

Bearing in mind that it is intended to be a beginners' book, and that much detail is therefore not to be expected in the more advanced and technical portions, these are really the best; indeed, the last two chapters give excellent summaries of the leading facts about the discharge of electricity through gases and about electrical oscillations. DAVID ROBERTSON.

OUR BOOKSHELF.

Lehrbuch der vergleichenden Mikroskopischen Anatomie der Wirbeltiere. Edited by Prof. Dr. A. Oppel. VII. Teil, *Sehorgan,* by Dr. V. Franz. Pp. x+417. Price 18 marks. VIII. Teil, *Die Hypophysis Cerebri,* by Dr. W. Stendell. Pp. x+168. (Jena: G. Fischer, 1913–14.) Price 8 marks.

WE have on former occasions expressed a high opinion of the "Comparative Microscopic Anatomy of Vertebrate Animals," now appearing under the editorship of Prof. Oppel. The parts here noticed (Nos. 7 and 8) deal with the eye and pituitary body, and maintain the high standard set by the earlier parts. In systematising our present knowledge of the various forms assumed by the eye in vertebrates, Dr. Franz has utilised more than 650 papers published in recent scientific journals, and in the light of his own researches grouped a multitude of facts together, so that his text and numerous illustrations form a consecutive treatise as well as a most valuable encyclopædia for reference. He describes the minute structure of each part of the eye in turn—the retina, vitreous body, pecten, choroid, ciliary body, etc., tracing the variations undergone by each throughout the ramifications of the kingdom of vertebrate animals. The opening chapter deals with the visual cells of amphioxus; the closing one with the structure of the eye of species in which the sense of sight has been impaired or lost from disuse.

Dr. Walter Stendell's monograph on the pituitary body is of particular value at the present time. Until some thirty years ago this apparently unimportant structure was regarded as merely an interesting morphological puzzle. Our estimate was suddenly changed in 1886, when Dr. Pierre Marie discovered that the remarkable disease he described under the name of acromegaly was accompanied by a pathological enlargement of the pituitary body. It was then realised that what was supposed to be merely a small vestigial organ had a direct power of regulating and influencing the growth of the body. Embryologists, morphologists, physiologists, and pathologists then concentrated their attention on it, and the results of their labours may be seen in Dr. Stendell's pages, particularly in his long bibliographical list. We are glad to note he gives due prominence to the pioneer researches of Sir Edward Schäfer and of Prof. P. T. Herring.

Thresholds of Science. Astronomy. By C. Flammarion. Pp. xi+191. (London: Constable and Co.) Price 2*s.* net.

THE name of the author provides a guarantee of the soundness of the principles and the accuracy of the details expounded in this elementary introduction to astronomy by the eminent French astronomer. The book is essentially one for young readers, and the subject-matter is presented in a manner both lucid and interesting. The numerous illustrations are good, and aptly illustrate the text.

Commencing with the physical conditions of the earth, its motion and the resulting phenomena are treated at length, special attention being paid to the functions of the sun. A survey of the heavens with the constellations follows, and our relation to the "fixed stars" is made plain. The members of the solar system are treated individually, and their relations to each other in the system are efficiently illustrated. While dealing with the moon M. Flammarion introduces an interesting feature in a revue of the various mythical "Journeys to the Moon." The book concludes with a brief discussion of comets, nebulæ, and star clusters.

Although, as we are told in a footnote, "M. Flammarion naturally uses French measures" throughout the book, and the equivalents of the kilogram and kilometre are given, it would probably have been better had our own system of units been employed. The exercise in mental arithmetic required to obtain an estimate of the magnitude involved is very liable to break the continuity of thought, especially among the class of readers for whom the book is intended.

Bacon's New Contour Wall Map of Scotland. Scale, 1 :316,800, or 5 miles to one inch. Size 48 by 60 in. (London: G. W. Bacon and Co., Ltd.) Price 16*s.*

THIS new edition of a well-known wall map will be welcomed in schools. It is drawn on a conical projection with true meridians of longitude and errorless parallels 55° 30′ and 58° north latitude. The main orographical features are shown in the familiar shades of green and brown, and sea depths in blue tints. The lettering is such that it does not interfere with the scheme of colouring, and the railways, which are shown in red, are easily followed. The map can be obtained mounted and varnished with rollers to hang on the wall, or mounted with eyelets and cut to fold.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Faraday's Views on Catalysis.

At the present time much attention is being given, both by chemists and by physiologists, to the mechanism of catalysis in heterogeneous systems. The interest of the question to physiologists is in connection with the mode of action of those catalysts produced by living organisms; these are called, for convenience, "enzymes."

The extraordinary insight shown by Faraday into the nature of the various phenomena with which he had to deal is well known and needs no further comment. But, on this ground, the paper which he published in the Philosophical Transactions of the Royal Society for the year 1834, entitled "On the Power of Metals and other Solids to Induce the Combination of Gaseous Bodies," deserves more consideration by modern investigators than it usually receives. The paper is also to be found in "Experimental Researches in Electricity" (vol. i., pp. 165–94), and the references given to quotations below refer to the numbered paragraphs in that reprint.

Although Faraday's work was published before the introduction by Berzelius of the name "catalysis," the combination of oxygen and hydrogen gases brought about under the influence of platinum and other solids, which is the subject of the paper before us, is clearly a case of this kind. In fact, the action of spongy platinum is given by Berzelius himself in illustration of the phenomenon.

The chief experimental fact of importance to the theory of the process, and demonstrated by Faraday in a number of different ways, is that the only condition necessary is the *perfect cleanliness of the surface* of the platinum (617). He points out that impurities of various kinds are readily condensed on the surface ("adsorbed," as we should say), from the air and even from ordinary distilled water. The presence of such films prevents that condensation of the gases which is requisite for their combination. In whatever way—mechanical, as by rubbing with polishing powders (591, 592, 593); chemical, by treatment with concentrated mineral acids (600); or by heat (596)—these substances are removed, the platinum is made active. Of special interest is the fact that making it either anode or kathode in dilute sulphuric acid (588) is particularly effective, the formation of "nascent" oxygen on the surface in the former case being the more powerful, as would be expected. The difference between the clean surface and the dirty surface is shown by the way in which water, or gases developed on the surface by electrolysis, enter into closer contact with the clean surface and form uniform films, instead of drops or bubbles.

It is pointed out in paragraph 617 that the intervention of electrical forces is excluded by the fact that both anode and kathode are active. Chemical reaction between the platinum and oxygen is also excluded by the fact that nitrous oxide and hydrogen are caused to combine (572). In paragraph 618 further evidence that the effect is not due to the intervention of platinum in a purely chemical way is given by the fact that "the effect is evidently produced by most, if not all, solid bodies."

The reader will probably call to mind that it has been held by some observers that this and similar activities shown by platinum are to be explained by the formation of intermediate compounds of the nature of oxides of platinum. The actual existence of such compounds has never been demonstrated, and the hypothesis did not commend itself to the acute mind of Faraday, whose explanation is of much interest. On account of the importance of the question I will quote the actual words used:—"They" (the phenomena under discussion) "are dependent upon the *natural conditions* of gaseous elasticity, combined with the exertion of that attractive force possessed by many bodies, especially those which are solid, in an eminent degree, and probably belonging to all; by which they are drawn into association more or less close, without at the same time undergoing chemical combination—and which occasionally leads, under very favourable circumstances, as in the present instance, to the combination of bodies simultaneously subjected to this attraction" (619). As we might put it now, gases are condensed on surfaces, losing thus the kinetic energy of their molecules, and, if capable of combining together, may be thus caused to do so. Could we have a clearer statement of adsorption and the part played by it in catalysis?

In further illustration of this "adsorption," Faraday proceeds to give some interesting examples of the condensation of water vapour and of air on the surface of various powders and on glass, pointing out in the latter case that there is no chemical affinity between air and glass. We note also that Faraday says that the vapour is condensed *upon* the substances. Again, "The gases are so far condensed as to be brought within the action of their mutual affinities at the existing temperature" (630), and "The platina is not considered as causing the combination of any particles with itself, but only associating them closely around it; and the compressed particles are as free to move from the platina, being replaced by other particles, as a portion of dense air upon the surface of the globe, or at the bottom of a deep mine, is free to move, by the slightest impulse, into the upper and rarer parts of the atmosphere" (631). As regards the adsorption of other substances on the platinum, we read: "In fact, the very power which causes the combination of oxygen and hydrogen, is competent, under the usual casual exposure of platina, to condense extraneous matters upon its surface, which, soiling it, take away for the time its power of combining oxygen and hydrogen by preventing their contact with it" (632). We have here analogous phenomena in the action of enzymes, where an easily adsorbed substance, such as saponin, prevents the action of the enzyme by obtaining possession of the surface itself and thus excluding the condensation of the molecules between which chemical action is to be brought about.

Although Faraday evidently regards condensation on surfaces as especially applicable to gases, it is clear that he considers the phenomenon to be of general occurrence. He does not appear to have met with cases of adsorption of substances from solution in liquids, but he says "an analogy in condition exists between the parts of a body in solution and those of a body in the vaporous or gaseous state" (657). Is this statement to be looked upon as an anticipation of van 't Hoff's theory of solutions?

I will conclude my quotations from the paper with the following, which is worth bearing in mind at the present day:—"I am convinced that the superficial actions of matter, whether between two bodies, or of one piece of the same body, and the actions of particles not directly or strongly in combination, are becoming daily more and more important to our theories of chemical as well as mechanical philosophy. In all ordinary cases of combustion it is evident that an action of the kind considered, occurring upon the surface of the carbon in the fire, and also in the bright

part of a flame, must have great influence over the combinations there taking place" (656). The last sentence is interesting in connection with the work of Prof. Bone on surface combustion.

It is, perhaps, rather to be wondered at, since Faraday had gone so far in the interpretation of the phenomena, that he did not take the further step and bring them into relation with surface tension, to which Thomas Young had already directed attention.

In the application of these facts to the theory of enzyme action, the view was first definitely put forward by myself, so far as I know, in a paper in the *Biochemical Journal*, vol. i. (1906), pp. 222–27, that the "combination" between an enzyme and its substrate is of the nature of an adsorption. This view has received more and more support from work done by various investigators since that time. To mention one fact only, it has been found in the cases of several different enzymes that their activity is exercised in liquids in which they are completely insoluble, so that it must be the surface of the particles which is concerned. We know also that, in water, enzymes in general are in the colloidal state, a state in which chemical reactions obey laws which interfere with that of mass action in its simple form.

It is very doubtful whether intermediate compounds of a chemical nature play any part in catalysis by enzymes. None, at all events, have been shown to exist. Moreover, such an explanation is of very rare application to catalysis of any kind. The hypothesis of the action of enzymes which is most in agreement with all the facts known at present may be stated somewhat as follows: the molecules which are to enter into reaction are condensed by adsorption on the surface of the colloidal particles of the enzyme and their final state of equilibrium is brought about at a greatly accelerated rate. Whether, as Faraday seems to hold, the close approximation, and high concentration, is in itself sufficient to account, by mass action, for the increased rate of reaction is a matter for future investigation. It may well be, as Hardy points out (Proc. Roy. Soc., vol. lxxxviii. B, pp. 174 and 175), that it is in the actual process of condensation itself that the molecules are subject to stresses which result in exceptional chemical activity; their chemical potential may very well be raised in the process. It appears to be a phenomenon of very general occurrence that it is in the very act of change of state that special activities are manifested. This is particularly obvious in living organisms, where a system in equilibrium is dead, but it applies also to non-vital systems.

I would finally point out that it should not be stated that the action of enzymes does not obey mass action. Mass action is universal in its application; but, in heterogeneous systems it is controlled by other factors, such as diffusion and surface adsorption, the latter factor playing the chief part in the velocity of reaction in micro-heterogeneous systems, such as those of colloids. The rate of the reaction is conditioned by the relative masses of the molecules condensed on the surface at any one moment of time. It will be seen that the difficulty of applying the law of mass action consists in the determination of the real active masses.

Tidal Friction and Ice Ages.

A CAREFUL study of the conditions of land height during the earlier stages of the Quaternary glacial period seems to show that the earth was then less oblate, *i.e.* the north and south polar regions stood higher than now, to the extent of as much as 10,000 ft. in places, while the equatorial regions stood lower, by some 500 ft. The spreading of ice-sheets from these high lands may well have been the initial cause of the cooling which produced the Glacial epoch.

Going further back in geological time, we find, as is well known, a series of long periods of epeirogenetic movement alternating with long periods of marine transgression. The last great change seems to have been continuous from Carboniferous times, with a girdle of land round the equator high enough to be heavily glaciated, through Mesozoic times, with a marine transgression, to Pliocene times, when the high land emerged at the poles.

Qualitatively, at least, it seems possible to read the late Sir G. H. Darwin's theory of tidal friction into these changes. By that theory, owing to the differential attraction of the moon on the tidal protuberances, the rotational momentum of the earth is gradually decreasing. This decrease may manifest itself in two ways, either by an actual decrease in the rotational velocity, or by a decrease in oblateness, *i.e.* by a movement of matter towards the poles.

It is probable that the earth's crust has a certain tendency to slide on its nucleus, and since the effect of tidal friction is chiefly felt in the crust, while the bulk of the momentum must lie in the heavy nucleus, it follows that the effect of tidal friction must be to tend to slide the crust round the nucleus parallel with the equator. As the crust must vary both in thickness and in the closeness with which it is attached to the nucleus, this means a thrust against the deeper and more closely attached portions. The thrust would tend to force some of the crust poleward on either side from the equator, *i.e.* to decrease the equatorial bulge.

But the friction between crust and nucleus is very great, and must in time result in an appreciable decrease in the angular velocity of the latter. Probably the action takes place in alternating steps—periods of constant rotational velocity, combined with a gradual thrusting of the crust poleward from the equator, alternating with periods of stability of the crust and gradual decrease in the rotational velocity. The former are periods of earth movement, mountain forming, and disturbance, resulting in the gradual deepening of the ocean over the equator and emergence at the poles; the latter are associated with a slow retirement of the ocean towards the poles, resulting in marine transgressions in middle and higher latitudes.

I have been able to accumulate a great deal of evidence which supports the theory I have outlined above on the geological side. I am, however, not sufficiently a mathematician to be able to satisfy myself that the cause, tidal friction, is commensurable with the effects, and I am begging the publicity of your columns to ask if someone better situated will help me in that respect.

C. E. P. BROOKS.

"Homeleigh," 3 Roseleigh Avenue,
Highbury, N., October 10.

AT the Editor's request I contribute a few remarks on Mr. Brooks's letter. The suggestion that tidal friction might be a cause of changes in the distribution of land and water is not new. It will be found in a "Note" in NATURE of April 25, 1889 (vol. xxxix., p. 613), where it is attributed to M. A. Blytt; and that may not be its first appearance. The character of the changes is that indicated by Mr. Brooks, but the mechanism by which they are effected is a little different. The hypothesis of a crust riding more or less freely on a nucleus is unnecessary, and difficult to reconcile with well-established results. Again, the frictional stresses do not operate directly to cause a flow of material towards or away from the poles, but indirectly by diminishing the speed of rotation.

The mechanical process may be followed very easily

without any mathematics. The surface of the ocean, apart from waves and tides, is at any time a figure of equilibrium answering to the speed of rotation at the time, more oblate when the speed is greater, less oblate when it is slower. Let us imagine that the lithosphere also is at some time a figure of equilibrium answering to the speed of rotation at that time. If the speed remained constant, the lithosphere would retain this figure, and the matter within it would remain always in the same configuration without having to support any internal tangential stress. Now suppose that the speed of rotation gradually diminishes. The surface of the ocean will gradually become less and less oblate. The lithosphere also will gradually become less oblate, but not to such an extent as to make it a figure of equilibrium answering to the diminished speed of rotation, while the matter within it will get into a state of gradually increasing internal tangential stress. The effect on the distribution of land and water will be that the depth of the ocean will gradually diminish in lower latitudes and increase in higher latitudes, the latitudes of no change being 35° 16′ N. and S.

The internal tangential stress in the matter within the lithosphere may increase so much that it can no longer be supported. If this happens a series of local fractures will take place, continuing until the lithosphere is again adjusted much more nearly to a figure of equilibrium, which will be less oblate than the original figure. The effect on the distribution of land and water will be that the depth of the ocean will increase rather rapidly and spasmodically in lower latitudes and diminish in higher latitudes.

Accordingly the kind of geological change which the theory of tidal friction would lead us to expect is a sort of rhythmic sequence, involving long periods of comparative quiescence, marked by what Suess calls "positive movements of the strand," in the higher latitudes, and "negative movements" in the lower, alternating witih comparatively short periods of greater activity, marked by rise of the land around the poles and subsidences in the equatorial regions. It is for geologists to say whether the facts known to them are consistent with this description or not.

A. E. H. LOVE.

The Age of a Herring.

IN the issue of NATURE for September 17 Prof. D'Arcy Thompson states that he is unable to persuade himself of the validity of Dr. Hjort's conclusions based upon the methods of determining the age of herrings by a study of their scale-rings.

It is, of course, impossible to attempt to deal in a few words with all the evidence brought forward in favour of these methods in recent years by different biologists, and we must, with regard to the herring, refer to our published papers,[1] where arguments are given in favour of the primary assumption that the age of a herring may be determined by counting the rings seen on its scales. The facts supporting this assumption are briefly:—

(1) For young individuals (up to age of three years) the results of age determinations by means of the scale-rings correspond with the results obtained by plotting frequency curves for the length measurements of the individuals.

(2) Scale examination of small herrings continued with short intervals during all seasons showed that the formation of the so-called winter rings took place during the winter, while the formation of the so-called summer belts commenced in the spring and continued during the summer months. That the summer belt is small at the commencement of the formation in May, while it is large on the completion of the formation in the beginning of autumn, has been proved by observations carried on during four years. Regarding the older fish, it has been difficult to proceed in the same manner as for younger fish, as the frequency curves fail to give any hints as to the age groups represented in a sample, while, on the other hand, the fishing season for the old herrings does not extend over all seasons of the year. The following facts point to the correctness of the assumption that the conditions here are strictly homologous to the conditions as regards the younger fish.

(3) Among the Norwegian herrings a great many

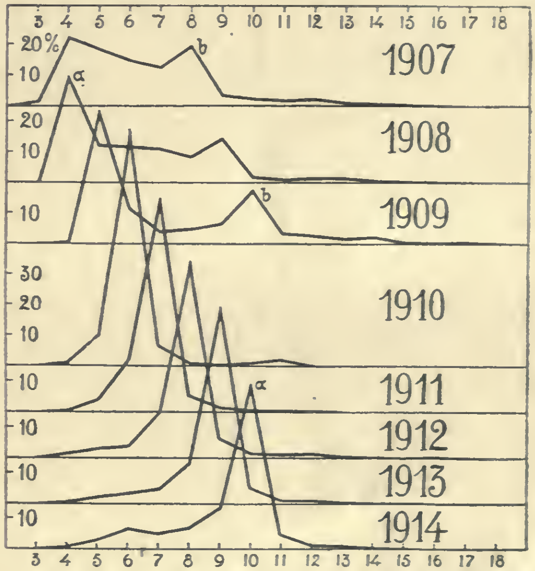

FIG. 1.—Showing the captures of Norwegian mature herrings for eight successive years, arranged in percentage frequency curves according to the number of rings on the scales (the numbers along the abscissa denoting the ring groups).

individuals had an abnormally small third summer belt on their scales. Herrings showing this abnormality have been very frequently observed during all the years from 1907 to 1914, but while the scales of these herrings in the year 1907 had only one summer belt outside the abnormal one in 1908, they showed two summer belts, and so on until the winter 1913–14, when they had seven summer belts outside. Thus these herrings, so easily distinguishable by their abnormality, have during the seven years of observation annually formed one summer belt on their scales, each belt being separated by a winter ring from the preceding and succeeding belts.

(4) By scale investigations on the Norwegian spring herrings (spawning herrings), carried out during the years from 1907 to 1914, results are obtained the main points of which are given in Fig. 1. This diagram is based upon all the material from 1907–13, while for 1914 part of the material was not worked up when the diagram was constructed (still the curve for this year is based upon more than 2000 individuals).

Lea, "Further Studies concerning the Methods of calculating the Growth of Herrings," *Publ. de Circonst.*, No. 66. Copenhagen, 1913.

The diagram shows, for each year of observation, the percentage frequency of the individuals according to the number of rings on their scales, the figures along the abscissæ denoting the number of rings, while the corresponding ordinates denote the percentages of all the individuals falling in each ring group.

The most prominent feature of this diagram is the regular movement of the primary mode (*a*) from 1908–14, as well as of the secondary mode (*b*) from 1907–09.

While in 1908 the individuals having 4 rings were the most numerous, in 1909 those having 5 rings, in 1910 those having 6 rings, in 1911 those having 7 rings, in 1912 those having 8 rings, in 1913 those having 9 rings, and in 1914 those having 10 rings predominate.

In the same manner the secondary mode (*b*), appearing in 1907 by the relative numerical strength of group 8, moves one class to the right for each of the years 1908 and 1909.

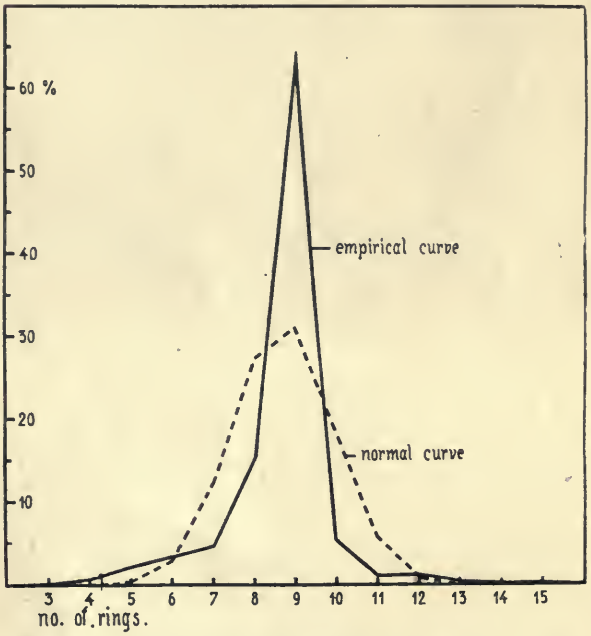

FIG. 2.—Comparison between the empirical ring curve for 1913 (in Fig. 1) and its corresponding normal variation curve.

It seems difficult to explain this regular movement of the modes, unless we assume that the two prominent modes represent two relatively abundant year-classes of herrings.

If this be true, then the material investigated leads to the conclusion that great fluctuations occur in the stock of Norwegian herrings with regard to the relative abundance of the different year-classes. That the magnitude of these fluctuations is astonishing and "very hard to imagine," is by no means an argument against the observed facts.

Prof. D'Arcy Thompson emphasises the regularity with which the so-called year-groups arrange themselves in a unimodal skew-curve, "just as the same fish group themselves also, according to size, in a unimodal but more normal curve." It seems to him "statistically improbable that a dozen separate generations of herrings, spawned in as many years, should have entered into the formation of the composite shoal in these curiously and regularly graded proportions." He finds it much easier to explain this fact by assuming that all the herrings (in a sample) were *of the same age and origin*, and that consequently the individual herrings vary about a certain modal number of rings, just as they also vary in a normal fashion about a certain modal size. He also emphasises the probability of an irregular age-curve for a population where large and irregular fluctuations occur in the annual birth-rate.

It might have been expected, then, that Prof. D'Arcy Thompson would have subjected the material published to a statistical analysis in order to convince himself of the correctness of his opinion regarding the similarity between the age-curves and the normal curves so usual in biology. He would then have found that no age-curve in the whole material of Norwegian herrings follows the usual law for biological variation. In some cases the age-curves present themselves by mere inspection as irregular (see Fig. 1, 1907, 1908, and 1909), while in other cases (when the curve is unimodal, as in Fig. 1, 1910–14) they are so entirely different from the normal frequency curve that it is totally impossible to replace the empirical curve by the corresponding theoretical one. This will be apparent from Fig. 2, giving the empirical age-curve for Norwegian herrings in 1913 (see Fig. 1) together with the normal curve for the same number of individuals, the same average and standard deviation, and the same arrangement of classes. In the following table the same data are given numerically:

Number of scale rings	Empirical frequencies in percentages	Theoretical frequencies in percentages	Difference empirical—theoretical values
3	0·1	0·0	0·1
4	0·7	0·0	0·7
5	2·2	0·4	1·8
6	3·4	3·0	0·4
7	4·8	12·5	− 7·7
8	15·4	27·4	−12·0
9	64·7	31·2	33·5
10	5·2	18·5	−13·3
11	1·2	5·8	− 4·6
12	1·3	0·9	0·4
13	0·5	0·1	0·4
14	0·2	0·0	0·2
15	0·2	0·0	0·2

The dissimilarity of the two curves is, in fact, so great as to exclude any idea of the age-curve following the usual law for biological variation. The feature that the curve is apparently unimodal, is due to the fact that one single group is so overwhelmingly abundant as to depress to a certain degree the irregularities actually existing in the frequencies of the other groups. By inspection of the age-curve for 1914 (see Fig. 1) it will be observed that the frequency of group 11, lying close to the modal group, is less than for the more extreme groups 6, 7, and 8.

For these reasons, as well as because of the regular movement of the modes, it seems to us impossible to explain the observed facts as a result of common variation, even if the help of a mathematical statistician were enlisted.

EINAR LEA.

Scientific Work and the War.

DR. CALMAN's plea (NATURE, October 22, p. 198) for the continuance as usual of the work of our learned societies, or even a wider plea for the calm prosecution of all our scientific studies, may be supported on many grounds, but the only one that I wish to emphasise is the moral effect thus produced upon those neutral nations whom our opponents seek to delude into the belief that we are panic-stricken. To the

reality of this effect the following sentences in a letter just received from a correspondent in Florence bear witness:—". . . e sapendo, d'altra parte, che l'Inghilterra sta fortemente sostenendo la sua bella lotta, senza perdere il tradizionale sangue freddo; per modo che la vita continua costà quasi inalterata. La regolarità, con la quale i periodici scientifici continuano ad apparire ne é la prova migliore." F. A. B.

THE CARE OF THE WOUNDED.

A FURTHER paper by Medical Inspector-General Delorme was read before the Paris Academy of Sciences on September 28, on the general subject of the treatment of wounds in war (*Comptes rendus de l'Académie des Sciences*, October 5, 1914).

The paper begins with a very welcome statement that the health of the French Army is excellent. "The persistent mildness of the weather since the war began, the extreme carefulness of the Government, the watchfulness of the Commands, from the lowest to the highest,—such fatherly watchfulness as you would not find, so intense and so alert, in any other campaign—the organisation and the regular methodical active working of the Army Medical Service, the great care given to the food-supply, the sites chosen for the troops—all these, up to now, have resulted in the maintenance of a perfect sanitary condition. The wounded Frenchman is a healthy man. Diseases are at a very low point. . . . Dysentery and typhoid are almost unknown: the proportion of cases has seemed to me to be even less than in time of peace." And, he adds, the spirit of the wounded men is perfect: it plays its great part in the work of a speedy and permanent recovery, "ce moral, qui est la traduction fidèle et tangible de la vitalité de l'homme." It is not the wounded who are broken-hearted: "le trouble n'est que dans le cœur des mères."

We are thankful to know that the general health of the French Army, and of our own Expeditionary Force, is thoroughly satisfactory. How long this blessing will last we do not know. But we may be quite certain that the Army Medical Services are working day and night for it, not in vain.

General Delorme's paper goes on to consider what more can be done for the wounded. He urges, very justly, that the large proportion of shrapnel-wounds and shell-wounds indicates the advisability of having a rather elaborate field-hospital system, as near the front as may be. Wounds of this kind, of course, are infected from the very moment of their occurrence: and it is a matter of the highest importance that they should be attended to, very thoroughly, at the earliest moment possible. The "first dressing" which may suffice for a cleaner wound, made by a bullet, will not suffice for them. The occasion may require the use of X-rays, the extraction of foreign bodies, the immediate administration of a protective serum or vaccine, and so forth: none of them to be delayed.

In the discussion of this communication the speakers were Laveran, Roux, and Landouzy; and the discussion was no less interesting than the paper. One, and that the worst, consequence of these infected wounds is, happily, under the control of a protective serum-treatment; and we may be sure that the money to provide that treatment will not be lacking. It is not simply a question of money: it is a question of what can be done, in this colossal fighting, to avoid loss of time in dealing thoroughly with so many infected wounds. As Landouzy says—and it is pleasant for an Englishman to read—"Il faut que, dans les armées des pays de Pasteur et de Lister, la Chirurgie active soit concentrée en partie et résolument vers l'avant, si l'on veut que l'asepsie et l'antisepsie des blessures de guerre soient possibles." STEPHEN PAGET.

THE TRANSIT OF MERCURY ON NOVEMBER 7, 1914.

MERCURY is one of the two planets which revolves round the sun in an orbit smaller than that of our earth, and consequently at a time of inferior conjunction generally passes just to the north or south of the sun. The reason why it does not always pass exactly between the sun and us is because its orbit is inclined at an angle of 7 degrees to the plane of the ecliptic, and the planet is only twice during a revolution at the cutting points or nodes, and is not necessarily at one of these points when passing on the near side of the sun.

When, however, conjunction does occur and the planet is near a node, it is seen to cross the sun as a small black spot, but it requires the use of a telescope to discern it. In May and November of each year the earth passes the nodal points, and it is only during these months that a transit can occur. On November 7 a very favourable transit will take place, and the whole phenomenon from start to finish will be visible from these islands during the interval comprising the two hours on each side of noon. Transits of Mercury are sufficiently rare to attract attention, as only about twelve occur in a century. The last one took place on November 12, 1907, and we shall have to wait until 1924, May 7, before another will be on view.

The planet makes first contact with the sun at 9h. 57m. 15s. on the morning of November 7 at a point on the sun's limb 156° from the north point of the sun counting towards the east. It takes the planet 2m. 14s. to place his whole disc completely on the sun. While it does not actually cross the centre of the solar disc, the time of its least distance from that centre is 12h. 3m. 22s. p.m. At 2h. 7m. 16s. p.m. the planet will have reached the sun's limb again, touching it at a point 255° from the north point, still reckoning in the same direction towards the east; it will take again 2m. 14s. to pass clear of the sun. It should be noted that the above times, although accurate enough for general observers, refer to the phenomenon as observed from the centre of the earth, and not as seen from the earth's surface.

Coming now to the method of making observations and the observations themselves, a word of warning should be given to those who are not familiar with making solar observations. No one should use a pair of binoculars or a telescope of any size unless proper precautions are taken; otherwise the loss of eyesight may be the result. It is better to make no attempt to watch the transit than to make risky observations. Proper dark glasses should be secured beforehand, and fixed firmly in position so that they cannot fall off at the critical time. A method devoid of all risk is to throw the solar image on a screen; in this way more than one observer can watch the transit.

In the *Comptes rendus* of the Paris Academy of Sciences for October 5 Monsieur Bigourdan summarises a series of the principal precautions which should be taken by those who wish to make useful observations. Such precautions are necessary because a transit of Mercury seems to be accompanied by various appearances the causes of which are not always well known. It is therefore advisable to eliminate so far as possible all possible errors which may arise through instrumental deficiencies.

He suggests first of all the method of observing the sun directly, and not by projection, for in the latter case delicate details are chiefly lost. To diminish the solar light he proposes a method of semi-silvering the outer surface of the objective, but he adds that this method holds good only when the sky is clear, otherwise observation would be impossible. The practical method of employing graduated and compensated dark glasses is chiefly recommended, and the greatest aperture of the telescope should be employed, having due regard to the heating at the focus, and the resulting cracking of the graduated glass.

While giving the preference to telescopes of large aperture, the results furnished by moderate or even small telescopes should not be neglected. Both reflectors and refractors should be brought into use. He directs attention to the importance of having diaphragms well blackened and suppressing for the time being any fixed accessories in telescopes which ordinarily serve for the illumination of the field, and which, situated in the path of the beam or in the vicinity of it would produce hurtful reflections. When an instrument can be reversed or can take up two positions successively to the right and left of its mounting, it should be utilised alternately in these positions, thus turning the whole optical system through 180°. Finally, he points out the importance of observing every appearance, however abnormal, by studying it in different positions of the telescope, with different eyepieces, dark glasses, etc. While the above precautions are particularly to be recommended for accurate observations, others of a secondary nature must not be forgotten.

With regard to the observations to be made during the planet's transit, those of first importance are the determinations of the accurate time of the internal and external contacts. Next come the measurements for the determination of the diameter and the flattening of the planet's disc. Rings (aureoles) around the black disc of Mercury form interesting objects for observation, and their intensity in relation to the neighbouring solar surface should be studied.

A spectroscopic survey of these rings would decide whether their existence was real or not, and the question of an atmosphere round Mercury could thus possibly be inquired into. Other points of interest relate to luminous appearances on the dark disc of the planet, possibility of satellites, occultations of solar spots, and faculæ by the disc, etc.

Successful observations of these and other phenomena help to further our knowledge of the movements and physical constitution of this the smallest of the planets.

A METEORITIC FALL IN LANCASHIRE

ON Tuesday evening, October 13, at 8.45, the inhabitants of Lancashire and Cheshire were alarmed by a sudden and vivid illumination of the heavens caused by a ball of fire moving slowly from about S.S.E. to N.N.W. It lit up the whole countryside and consisted of several outbursts, the final one being the brightest flash. Then a short interval afterwards, the estimated periods varying from a few seconds to four minutes, according to the distances of the observers, there was a tremendous report, as though a thunder-like explosion had occurred in the region a few miles west of Wigan.

This was followed by a series of rumblings extending apparently back along the flight of the luminous object. At several places the windows are stated to have been shaken, and the vibration was such that it presented some similarity to an earthquake shock.

Numbers of persons in Manchester, Liverpool, Halifax, Northwich, Bolton, Macclesfield, and other towns witnessed the event and heard the noise, and in the present agitated state of the public mind, all sorts of ideas were formed as to the nature of the phenomenon.

A large detonating meteor had, notwithstanding the rather cloudy state of the atmosphere, not only penetrated the lower region of the air, but had resisted complete disruption and fallen to the ground. It was discovered on the following day at Appley Bridge, four miles W.N.W. of Wigan. An employee of Mr. Lyon of Halliwell Farm noticed a newly turned up mound in a field and on examination, he saw a reddish mass of strange material lying in a hole about 18 in. below the surface. On being dug out the object weighed about 33 lbs. and in appearance looked like a rough piece of burnt iron. Subsequently, the county police took possession of the strange visitor, and it has since been handed over to the curator of the Godlee Observatory, Manchester, for proper investigation.

My preliminary discussion of the first observations received indicated that the meteor penetrated to a point so low in the air that it probably fell in the region twenty miles west of Manchester. This conclusion was mentioned in a letter to the Manchester papers, and the discovery of the meteorite a few miles west of Wigan fully justified the prediction. Several of the observers say that the object lost its luminosity when still at an apparently considerable height. This appears to show that the motion had so far slackened that combustion had visibly ceased, and the object fell to the ground in an opaque, cooling condition. Evidence of this is also furnished by its penetrating the soil to a depth of only 18 in. Several well-observed meteoritic falls have been of merely terrestrial velocity amounting to 400 or 500 ft. a second, which is something different from the velocity of 26 miles a second possessed by these bodies in planetary space. The descent of objects of this class is often vertical or nearly so, and their original velocity and direction are apparently quite changed by the new conditions impressed on them during their disruption when very near the earth's surface.

I have collected a large number of observations of the flight of the object, from which it appears that its direction was from about azimuth 335°, counted west from south, or from S.S.E. to N.N.W., and the probable radiant was at $348° + 2°$ in the western region of Pisces. The course of the meteor was from near Stoke to the place of its fall, a length of 49 miles traversed at a velocity of about 8 miles a second. The height declined from 29 miles to 0.

The object is said to have made a slanting hole in the ground, and this would accord with an angle of some 37°, which a radiant at $348° + 2°$ would indicate. But the angle of the meteor's descent must have probably become much steeper after its entry into our atmosphere as an effect of the resistance encountered and terrestrial attraction. Several disruptions of its material undoubtedly occurred before the final outburst; these reduced the size and varied the shape of the object and may well have influenced the line of flight.

The radiant in Pisces yields many fireballs in September, and one was seen by many observers on September 8 last. Daniel's comet of 1907 has an orbit which approaches near the earth's orbit on September 12 and may possibly be responsible for some of the large meteors observed in September and at a later period.

Previous meteoric falls have occurred as follows in England, and I give the last recorded case in Ireland:—

1795 December 13, Wold Cottage, 56 lbs.
1830 February 15, Launton.
1835 August 4, Aldsworth.
1876 April 20, Rowton, $7\frac{3}{4}$ lbs.
1881 March 14, Middlesbrough, $3\frac{1}{2}$ lbs.
1902 September 13, Crumlin, Ireland, $9\frac{1}{2}$ lbs.

W. F. DENNING.

NOTES.

A COURSE of twelve Swiney lectures on geology will begin on Saturday, November 14, in the lecture theatre of the Victoria and Albert Museum, South Kensington, by Dr. J. D. Falconer, who will take as his subject, "Land Forms and Landscapes." There will be no charge for admission to the course.

M. BOUTROUX, member of the Institute of France, and professor in the University of Paris, has accepted an invitation of the British Academy to deliver the first of the recently endowed annual philosophical lectures. His subject will be "Certitude et Verité," and the lecture will probably be delivered early in December next.

ANNOUNCEMENT is made that the Serbian Government is in immediate need of the services of qualified bacteriologists and physicians experienced in the treatment of epidemic diseases. Conditions of service and remuneration will be made by arrangement. Applicants should communicate with the Secretary of the Serbian Legation, 195 Queen's Gate, London, S.W.

A SHARP earthquake was felt over the whole of northern Italy at 10.20 a.m. (9.20 Greenwich mean time) on October 27. The scanty reports which have appeared in the newspapers show that it was sensible from Venice to Elba, and from Turin to Ancona—that is, over an area of not less than 70,000 square miles. The epicentre was apparently near Lucca, or between that city and Bologna.

COL. W. B. BRYAN, who, as chief engineer of the Metropolitan Water Board, had much to do with the improvement of the London water supply, died suddenly on October 27. Col. Bryan was to have delivered the Thomas Hawksley lecture on "Pumping and other Machinery for Waterworks and Drainage," before the Institution of Mechanical Engineers on Friday last, but the lecture has now been cancelled.

DR. F. B. POWER will retire from the directorship of the Wellcome Chemical Research Laboratories on December 1, in order to return to the United States of America. His period of service dates from the foundation of these laboratories by Mr. H. S. Wellcome in the spring of 1896. Dr. Power will be succeeded by Dr. F. L. Pyman. The character and policy of the Wellcome Chemical Research Laboratories will continue as in the past.

A REUTER message from Stockholm reports that the Swedish scientific institutions which have to award the Nobel prizes in December have decided, in view of the European situation, to postpone the distribution of the prizes for 1914 for literature, medicine, chemistry and physics until next year. It is now proposed to hold the formal presentation of the prizes every year in the month of June instead of on December 10, the anniversary of M. Nobel's death, when the awards will merely be announced.

A GENERAL discussion on the hardening of metals has been arranged by the Faraday Society, to be held on Monday, November 23, at the Chemical Society, Burlington House, London, W. The president, Sir

Robert Hadfield, will preside over the discussion, and among those who will take part therein are Prof. Ernest Cohen, of Utrecht, Dr. G. T. Beilby, Prof. J. O. Arnold, Prof. H. C. H. Carpenter, Dr. C. H. Desch, Prof. C. A. Edwards, Mr. H. L. Heathcote, Mr. J. C. W. Humfrey, Dr. T. M. Lowry, Mr. Andrew McCance, Dr. W. Rosenhain, and others.

THE Dorset Field Club will award in May next the "Cecil" medal and prize of 10*l.* for the best paper on radium: its present position, supply, and cost; with any recent discoveries on its curative effects. The competition is open to any person between the ages of seventeen and thirty-five on May 12, 1914, who either was born in Dorset or had on the date mentioned lived in the county for the preceding twelve months. Further particulars may be obtained from Mr. H. Pouncy, the *Chronicle* Office, Dorchester.

BY the will of Mr. W. Erasmus Darwin, eldest son of Charles Darwin, the Royal Society of London is bequeathed the sum of 1650*l.*; his nephew, Mr. C. Galton Darwin, receives the portraits of Charles Darwin by Lawrence and Ouless, as well as Darwin's medals, Royal Society's candlesticks, snuff-box, christening mug, autobiography, notebook on children, two early sketches of "The Origin of Species," two vols. of "Hooker's Correspondence," the family Bible, the old Dutch brass-bound box containing the family papers, large silver soup tureen, the counterpane worked with the coat-of-arms, the letters written home from the *Beagle*, and pictures and miniatures. The desire is expressed that these relics should always be kept in the family.

A RESEARCH prize of the value of 200*l.* has been placed by Sir Robert A. Hadfield, past president, at the disposal of the Iron and Steel Institute, to be awarded by the council for original research work on the different combinations of carbon in iron, steel, and alloys of iron with other elements. It is proposed that the prize shall be awarded at the annual meeting of the institute in May, 1916, for the best report presented before February 1, 1916. Sir Robert Hadfield is prepared to offer a second prize for the report next in merit to that which gains the first prize provided it is adjudged to be really meritorious. It is suggested that the work should be in continuation of, or based upon, the work of previous investigators. The object of the prize is to stimulate the study of carbides in iron and iron alloys generally, also with a view of discovering the best method of determining the forms and combinations in which carbon occurs in iron and steel. It is desirable to define the composition of these combinations more accurately and to ascertain whether other carbides exist which have hitherto not been identified. The study of the molecular constitution of the carbides will also fall within the range of the investigation. It is hoped that the results obtained will throw much light on the cause of hardness of steel, also on the nature and form of carbon combinations with iron and its alloys. Intending competitors should communicate, in the first place, with Mr. G. C. Lloyd, secretary of the Iron and Steel Institute, 28 Victoria Street, London, S.W.

Science of October 16 contains a memorial notice of the late Dr. Theodore Nicholas Gill, who died in Washington on September 25, in his seventy-eighth year. Although originally a law-student, Gill at an early age directed his attention to zoölogy, and in the winter of 1857–58, an expedition to the West Indies for the purpose of collecting shells and other natural history objects afforded him an opportunity of turning his inclinations to practical account. This was succeeded by a visit to Newfoundland in 1859, and in the following year he signalised his special interest in ichthyology by the preparation of a report on the fishes of the northern boundary for the U.S. State Department. Of wider interest was his catalogue of the fishes of the eastern coast of North America from Greenland to Georgia, published in 1861, of which a revised issue appeared in 1873. This and other works laid the foundations of his revised classification of fishes, which has been taken up and elaborated by Dr. D. S. Jordan and other American ichthyologists, and, according to the notice in *Science*, has now been accepted by European students of ichthyology. It must not, however, be imagined that Gill's work was restricted to fishes; on the contrary, it was unusually wide, embracing such diverse subjects as West Indian molluscs, the classification of mammals, and zoogeography. In 1861 Gill was accorded the chair of zoology at the Columbian (George Washington) University, Washington, a position he held until 1910, when he became emeritus professor.

SIR ERNEST SHACKLETON left Buenos Ayres for South Georgia on October 27 to carry on his trans-Antarctic enterprise. In a message to the *Daily Chronicle* of October 29 he announced some changes in the plans of the expedition. Instead of the *Endurance* returning to South Georgia and Buenos Ayres, after landing the members of the expedition, as was originally intended, she will winter in the Antarctic. Sir Ernest stated that on arrival at South Georgia all the dogs will be landed on one of the small islands of the group and left ashore. The geologists of the staff will also remain at South Georgia. The *Endurance* will then proceed south to examine the pack-ice and see whether it is loose enough to go into without unnecessary delay. After an examination of the pack the *Endurance* will return to South Georgia to pick up the members of the expedition and the dogs. The *Endurance* will be coaled to her fullest capacity, and, proceeding south again, will push right into the pack, keeping as much eastward as possible, in the hope of meeting more open water than is probably to be found further westward. Sir Ernest hopes to winter the vessel in 77·30° S. latitude, and if this point is gained at a sufficiently early date the transcontinental journey may be started this season. Should the ice conditions be too unfavourable, the journey will not be begun until October of 1915. The Argentine Government has provided the expedition with a wireless receiver, with which it will be possible to receive communications and time signals while the expedition is in the Antarctic.

IN the September number of *Folk-Lore* Miss C. S. Burne continues her valuable studies of the geograph-

ical distribution of British folk-customs. In this paper she deals with the customs known as souling, clementing, and catterning, practised in parts of the western midlands in November. They exhibit an example of successive layers of imported custom superimposed on a foundation of indigenous custom. First come the ancient, almost prehistoric, autumnal celebrations of the Old and New Year, probably always combined with a Feast of the Dead. Then Christianity transforms the pagan feast into the festival of Hallowmass. Next we meet with that combination of newly introduced subsidiary cults with newly organised and specialised crafts, which marks the progress of civilisation in the Middle Ages. Thus St. Clement and St. Catherine come into local prominence. Finally comes the period of decay, when the theological changes of the sixteenth century shatter the religious side of the kindly old customs, while simultaneously the centralising despotism of succeeding centuries and a civilisation growing more and more complicated deprive these rites, once so important, of any real significance, and they dwindle away or are kept up only by the most conservative part of the population, the children, wherever their elders allow them to benefit by them.

IN *Ancient Egypt* (part iv.) Prof. Flinders Petrie concludes his instructive review of the analogies between the culture and beliefs of ancient Egypt and those of certain African tribes. Such analogies are indicated by royal functions, beliefs, and material products. Among the royal functions attention is directed to the widely spread African customs in connection with the priesthood of the chief, his removal before he attains old age, and the concealment of the fact of his death; in sister marriage; in the importance assigned to the royal placenta, the leopard skin, and the ox tail; and in the use of the saw-fish as an emblem. Among beliefs we find similar analogies in the conception of the mundane spirit world; animism; the ancestral spirit; the roads for the dead; the ideas about twins, animal or human; the ram-headed god; the bull god; totemism and animal clans; the sanctity of the sycamore and the fig-tree; the sacrifice of red cattle; and divination by objects thrown. Egyptian culture, again, is connected with that of other parts of the continent by its pottery, mud toys, wooden head-rests, the wooden hoe, double process spinning, the use of the flat ground-loom, mosquito-nets, harpoons, drag and hand nets, basket traps, ring snares, and the ornamentation of the head by means of a cone. Individually these analogies may be of slight importance, but their cumulative effect is considerable. These various transfers of culture seem to have taken place in at least three periods: under the twenty-fifth dynasty at Napata, in the sixth century B.C., and after the introduction of Christianity.

PART 3 of vol. vii. of the Journal of the College of Agriculture, Tohoku Imperial University, is devoted to a synopsis of the Japanese chrysopid Neuroptera, with descriptions of several new species, by Mr. H. Okamoto. In connection with this may be mentioned a catalogue of books on entomology, chiefly from the library of the late Mr. Herbert Druce, issued by Mr. F. Edwards, High Street, Marylebone, W.

LIFELIKE photographs of grey-lag geese and of a specimen of the greater courlan (*Aramus giganteus*) recently received at the London Zoological Gardens form some of the most striking features in the October issue of *Wild Life*. The reader should, however, not have been left in the dark as to the native home of the courlan, and the attention of the editor may be directed to the need of greater care in proof-reading, as exemplified by the repetition on p. 32 of the statement that the sand-lizard is a slow mover, and of the substitution of "specimens" for "species" in the middle of p. 34.

INVESTIGATIONS carried on by Mr W. E. Collinge with the view of ascertaining the nature and quantity of the food of nestling sparrows have shown that in fruit-growing districts one hundred of these birds will consume nearly 2000 insects, and in suburban neighbourhoods about one-third of that amount. That sparrows are far too numerous is fully admitted; but it is suggested that if their numbers were considerably reduced they might be included in the list of benefactors. This and other information on the subject will be found in the October issue of vol. xxi. of the Journal of the Board of Agriculture.

AN excellent piece of systematic work is formed by Mr. A. H. Howell's revision of the so-called American harvest-mice, constituting the genus Reithrodontomys, published by the Smithsonian Institution as No. 36 of the *North American Fauna*. These mice, of which no fewer than fifty-five distinguishable forms are recognised, are chiefly a North American type, although the group also ranges through Central America to the northern States of South America. In the main essentially field-mice, they are in most districts only moderately numerous, although in a few they make their appearance in large numbers. As a rule, they do little harm, feeding for the most part on plants of no value to man.

IN *Symons's Meteorological Magazine* for July last Mr. L. C. W. Bonacina asked readers who had been in India whether lightning casualties, notwithstanding the severity of tropical storms, are not much rarer there than with us. He pointed out that many persons agree that thunderstorms in England are much more dangerous than in India. In the issue for October a correspondent ("G. G.") states that in the course of his travels in various parts of India, during a period of several years, he had only known or heard of one case of death by lightning, although a few high buildings, notably near Delhi, and tall trees in mountain districts, had been struck. He therefore answers Mr. Bonacina's question in the affirmative, the reason given being that thunderstorms occur higher up in the air. He states that he has never seen lightning in India so near the earth as he has in England.

DURING this summer experiments have been made with Langley's original "aerodrome" of 1903, and have proved that this scientifically designed pioneer machine is capable of flight with precisely its

original propulsive plant, wings, and rudders, and with 40 per cent. extra aggregate weight due to floats and their attachments. An account of these experiments is given in the *Scientific American* for October 10.

MESSRS. G. MICHAUD and F. Tristan, writing in the *Scientific American,* describe photographs and observations on the absorbing power of different flowers for invisible light. They find that the majority of flowers come out dark when photographed in ultra-violet light, but that a certain number of yellow flowers reflect the ultra-violet rays in a marked degree. In the case of the Compositæ this property is only exhibited by the exterior corollas. On the other hand, most flowers of any colour appear to reflect infra-red light to an equal degree.

IN the *South African Journal of Science* for September (vol. x., 14) Mr. Pedro Luis de Bellegarde da Silva advocates the use of wireless telegraphy in connection with the surveying operations now in progress in the province of Mozambique. At present these operations involve considerable delay owing to the peculiar nature of the country, and it is suggested that a distributing station at some place, such as Lourenço Marques together with small portable wireless outfits would enable the survey to determine the longitudes of many points in the province with greater expedition and accuracy than is possible with the present use of chronometers.

"THE Propagation of Disturbances in Dispersive Media" forms the title of No. 17 of the "Cambridge Tracts in Mathematics and Mathematical Physics," by T. H. Havelock (Cambridge University Press, 1914; pp. viii+87; price 3*s*. 6*d*. net). In it the author applies Fourier analysis to investigate the changes of form of a disturbance propagated in a medium in which the wave velocity is a given function of the wave-length. The theory of groups of waves of the most general type is thus discussed, and applications to optical problems are considered.

PART 213 of the Proceedings of the American Philosophical Society contains a paper by Prof. A. E. Kennelly and Mr. H. S. Sanborn, read before the society on April 24, which gives the results of a research carried out at Harvard University in 1911 on the effect of air pressure on the heat carried away from a hot wire by an air current blowing across it. In the original experiments of Prof. Kennelly and his pupils in 1909 it was shown that the watts which had to be spent in the wire to keep its temperature constant (400° or 500° C.) when air blew across it at a speed v between 200 and 2000 cm. per sec. varied as $\sqrt{v}$, but at lower speeds as $\sqrt{v+30}$. As Boussinesq in 1901 showed that the heat loss should also vary as the square root of the density of the fluid used, the present observations were made in a tank at various pressures, and it was found that for pressures above atmospheric the law held, but at lower pressures the power of the density was more nearly 0·4. They conclude that the constant of their heated wire wind velocity measurer or anemometer requires to be corrected for both temperature and pressure of the air. The effect of moisture in the air appears, however, to be small.

FOR many years there has been periodical agitation for the construction throughout the country of large granaries in order that there might be no possibility of a famine in the event of war. So far as the war has gone, the pressure of the Navy has shown that those who contended in favour of absolute ensurance of the command of the sea, in preference to such tentative measures, were right. Nevertheless, the immense granaries, which are increasing in number at our great shipping ports, are welcome on account of the facilities they afford for the discharge and distribution of grain, and for ensuring an adequate supply at the outset of war. The latest of these granaries, built by the Clyde Navigation Trustees at Glasgow, is described in *Engineering* for October 30. This granary has a total length of 312 ft., a width inside of 72 ft., and a total storage capacity for 31,000 tons of grain. While not so large as corresponding arrangements in Canada and the United States, the structural details of the Glasgow granary and the design of its machinery for discharging grain from ships and distributing it into and out of silos, are thoroughly representative of the best practice of the day, and of great and prolonged experience.

A LIST of the titles of English, American, French, and German medical and other scientific periodicals, together with prices of subscription, including postage to any part of the world, has been issued by Mr. H. K. Lewis, 136 Gower Street, London. Though only the leading publications are included, the list contains nearly 300 names. The periodicals published in Germany cannot be supplied during the war. The list will prove of particular service to librarians and of interest to medical men generally.

OUR ASTRONOMICAL COLUMN.

A NEW COMET.—M. Bigourdan communicates to the *Comptes rendus* for October 27 (vol. clix., No. 17) the substance of a telegram received from M. Comàs Solà, director of the Fabra Observatory, Barcelona, recording the discovery of a comet in a region of the sky recently occupied by Encke's comet. Its position on October 25 at 16h. mean Barcelona time is given approximately as R.A. 11h. 27m., and declination +50° 36′, and the movement is in a south-south-east direction at the rate of 5° a day. The comet is stated to be visible with a pair of opera-glasses.

THE COMET RECENTLY OBSERVED AT THE CAPE.—In this column on October 8 (p. 151) we recorded the appearance of a bright comet observed at the Royal Observatory, Cape Town, and published an ephemeris up to October 13, computed by Mr. Wood, of Johannesburg. The comet was stated to be fading, and at the same time to be rapidly decreasing its southern declination. This object has now been recorded from Barcelona, where it was photographed on October 17 last (*Comptes rendus*, vol. clix., No. 16, October 19). The note by M. Comàs Solà, presented by M. Bigourdan, to the French Academy, records its position as being R.A. 21h. 53m. 12s., declination −3° 14 at 8h. 9m., Barcelona mean time, the place

being determined from a photograph which showed the comet with a tail. Its direction of movement is given as north-north-west.

A LITTLE-KNOWN PIONEER OF SPECTRUM ANALYSIS.—While we owe the birth of spectrum analysis to Sir Isaac Newton (1642–1727), the first use of the slit to Wollaston (1802), and the first accurate mapping of the solar spectrum to Fraunhofer (1814), the name of the young pioneer, Thomas Melville, who followed closely after Newton is nearly forgotten. Although Melville died in 1753, at the age of twenty-seven, he was the first to employ the prism in laboratory research, for he undertook the examination of various flames, introducing sal ammoniac, potash, alum, etc., into burning spirits. He was undoubtedly the first to observe the yellow soda flame and notice its definite frequence in flames and its position as regards other colours. His name is briefly mentioned in Sir Henry Roscoe's "Spectrum Analysis," and Miss Clerke's "History of Astronomy," gives him full credit for his work. It was in reading the latter book that the attention of Mr. John A. Brashear was directed to the reference to Melville. Through Mr. Carnegie and Dr. Hew Morrison, the latter being principal librarian of Edinburgh, Mr. Brashear was enabled to obtain copies of Melville's essays read before the Medical Society of Edinburgh on January 3 and February 7, 1752, on observations on light and colours, in which appears the remarkable observation of the peculiar sodium light. These papers are now reprinted in the current number of the Journal of the Royal Astronomical Society of Canada (vol. viii., No. 4, July-August), and a very good service has been done by making them available to everybody.

DISPLACEMENT OF SPECTRUM LINES AT THE SUN'S LIMB.—Messrs. J. Evershed and T. Royds describe in Kodaikanal Observatory Bulletin, No. 39, some further researches they have been carrying on with regard to displacements of the spectrum lines at the sun's limb. Two explanations have been suggested to account for these shifts, one view being that they are due to pressure and the other due to motion in the line of sight. In this paper the authors state that the pressure theory presents a much more rational explanation of the phenomenon than the motion theory, but hold that there are difficulties in accepting the former, which have not been lessened, but largely increased by further research. The authors consider that the relative shifts of different lines at the limb have no particular meaning when determined by reference to lines at the centre of the disc, for these latter have shifts peculiar to themselves; the measures they have made show that the absolute shifts of the lines at the limb referred to a terrestrial standard show no relation to pressure shifts, and, further, the absolute shifts do not increase with the wave-length. In the investigation now published they determine the limb shifts by combining measures of limb minus centre shifts, with the centre minus arc shifts, the algebraical sum representing the absolute or limb minus arc shifts. They deal with the limb shifts in relation to the intensity of the lines, the relation between limb shifts and pressure shifts, limb shifts in relation to wave-length, and the shifts of the cyanogen bands. The conclusions they arrive at are that both the so-called cyanogen bands and the iron lines show shifts which they attribute to a movement of recession from the earth. While the view that the solar gases are actually repelled by the earth receives some support from other lines of evidence, they consider an alternative hypothesis, namely, that the sun's gravitational field affects the wave-length of the light emitted in accordance with Einstein's theory of relativity.

CLIMATOLOGY.

A PAPER by Dr. J. H. Garrett (Medical Officer of Health) on "The climate and topography of Cheltenham and its near neighbourhood" is published in the Proceedings of the Cotteswold Naturalists' Field Club for 1913 (vol. xviii., part ii.). The tables for thirty-five years (1878–1912) are derived from the records contained in annual health reports, or from the summarised values issued by the Meteorological Office. The figures show, as the author points out, that as regards the mean monthly maximum and minimum temperatures, the alternations from one season to another are very gradual. For the years 1892–1912 these were, respectively:—January, 43·6°, 33·6°; July, 71·6°, 53·4°; absolute maximum, 93° in September, 1911, minimum 6·5° in February, 1895. The annual rainfall shows considerable variation: 19·5 in. in 1892, 37·9 in. in 1882, normal for thirty-five years, 26·8 in. The prevalent wind directions are S.–W., those from N.–E. are comparatively few, while calms are very frequent. The average yearly sunshine (1903–12) was 1553 hours. Dr. Garrett remarks that quite a different climate is experienced on the Cotteswold Hills, within four miles of the centre of the town.

An elaborate discussion by Dr. V. Conrad of the climate of Carinthia, being part vi. of the valuable climatology of Austria, has been published by the Central Meteorological Institute of Vienna. This mountainous province covers an area of 10,327 km², of which 53·7 per cent. is above the level of 1000 metres. Like other Alpine countries it partakes of the sea climate of western Europe and of the land climate of eastern Europe, and is subject to abrupt contrasts within short distances. Tröpolach, for instance, in the Gail Valley, with an eastern aspect, has a mean January temperature of 18·7° F. and a winter temperature of 22·3°, while Pontafel, 7½ miles S.S.W., with a south exposure, has a January temperature of 28·6° and a winter temperature of 30·6°. The mean absolute yearly range of temperature in some of the valleys amounts to above 50° C. (90° F.); the absolute extremes recorded were below −22° F. and above 95° F. The yearly distribution of rainfall is well shown by a tinted map, referring to the period 1876–1900. With few exceptions there is a tendency towards increase of rainfall from north to south. The driest parts are the Noric Alps and neighbouring districts, with 31–35 inches of rain; the wettest parts are in the south-west, with 58–78 inches. The province possesses several long series of observations, *e.g.*, for Klagenfurt since 1813, but there is only one sunshine recorder, which is at the latter station.

Dr. Filippo Eredia has recently contributed to the *Rendiconti* of the Accademia dei Lincei (vol. xxiii.) two interesting memoirs on the distribution of cloud in Italy. The papers show the seasonal and annual distribution for 132 cities, and the orographic influence on the monthly mean values at a number of stations in the valley of the Po. In the latter region, on the Adriatic, central and lower Tyrrhenian, and Ionian slopes, winter is the season of most cloud. On the upper Tyrrhenian slope and on those near the Alps, spring is the cloudiest season. At Alpine regions and those under the direct influence of mountain systems there is generally least cloud in winter and in summer at other stations. The mean annual distribution and amplitude are shown by diagrams.

Another paper by Dr. Eredia, on the climate of Southern Italian Somaliland, is published by the Colonial Ministry of Rome as No. 14 of *Rapporti e Monografie coloniali*. The observations include *inter alia* those made by the Italian expeditions and at stations afterwards established, and are carefully

discussed under six separate elements. The climatological conditions are dominated by the N.E. monsoon (December–March) and the S.W. monsoon (June–September). The author points out that the temperature is very regular, there being only a difference of a few degrees between the means of the hottest and coldest months. The absolute maximum and minimum quoted during 1910–12 at six selected stations are 98·6° (in April) and 59° (in August), both recorded at Brava. The rainfall reaches its maximum values in April and November; the first rainy period is followed by falls of decreasing intensity and frequency in the coastal districts, and the second period by very scanty falls in the interior and extreme dryness on the coast. The largest yearly mean quoted is 30·1 in. (on fifty-two days) at Balad, and the smallest, 10·6 in. (on thirty-three days) at Giumbo. Generally speaking, rain falls in eight months on the coast and ten months in the inland districts.

The Bulletin of the Italian Royal Geographical Society for August contains a useful contribution to the climatology of Ethiopia by Dr. Eredia and Dr. De Castro. The results are chiefly based on observations made partly at Addis-Abeba and partly at Addis-Alem, from November, 1901, to June, 1911, excepting between July, 1904, and April, 1905, with instruments supplied by the Italian Meteorological Office. Monthly results for each year are given for temperature and rainfall, and in a less complete way for humidity and wind-direction. The mean annual temperature is 62·1°; highest mean monthly maximum, 80·1 (May); lowest mean minimum, 42·8° (December); absolute maximum, 100·4° (September); absolute minimum, 32·0° (December). The annual rainfall is 47·7 in., on 148 days. The authors' division and description of the seasons give a good general idea of the climate: winter (October–December), low temperature and scarcity of rain; spring (January and February), moderate temperature and relatively small rainfall; summer (March–June), high temperature and relatively large rainfall; autumn (July–September), moderate temperature and abundance of rain. The division of the year into seasons by the natives is essentially based on the occurrence of rainfall periods.

An article by Prof. Karl Dove, on the climate of German South-west Africa, was contributed to *Himmel und Erde* of December, 19, 1913. The protectorate extends from 17° to 29° S. latitude, but its position on the west side of the continent greatly modifies its climatological features, as compared with those on the eastern shore. Near the coast the cold water of the Benguella drift-current reduces the temperature considerably; but the inland parts owe their relatively low temperature to their great elevation above the sea. The annual range is very regular, and the approach of summer or winter has little interest for the inhabitants compared with the date, duration, and amount of rainfall. The heavier falls mostly occur between January and March; irrespective of small variations, Prof. Dove states that, with the exception of the extreme south, six- to seven-tenths of the year's rainfall may be referred to those three months. In large tracts of the western zone the annual fall does not exceed eight inches, and in some years little or no rain falls, not only in the coastal districts, but also in the interior of the country.

A very interesting and useful work on the climate, typhoons, and earthquakes of Formosa, with tables and diagrams, has recently been issued by the Government-General of that island. The meteorological service was organised in 1906 under an Imperial Japanese ordinance; observations are made at ordinary stations, lighthouses and rainfall stations, and the work is carried on almost entirely at Government expense. The central observatory at Taihoku receives and discusses all observations and also receives a number of telegrams and issues weather forecasts and storm-warnings for the whole island. The climate is subtropical, and may be divided into two seasons; the seven months April to October may be regarded as summer, and the five months November to March as winter. Throughout the island the mean monthly temperature rises to 68° F. in April; from June to September it ranges between 79° and 82°. The highest readings reach about 95°, and in rare cases exceed 98°. In winter the variations between the north and south of the island become more apparent; in February, the coolest month, the mean is about 58° in the north, and 68° in the south. The lowest readings in the north do not usually fall below 41°, and in the south not below 49·6°. In winter the N.E. monsoon brings rain to the northern parts, and in summer the S.W. monsoon and thunderstorms bring abundant rain to the south; the island, therefore, possesses two rainy seasons, each differing in time and place. Formosa lies in the highway of typhoons, and is often visited by those destructive storms; during seventeen years (1897–1913) thirty remarkable storms occurred during the months June to October. Earthquakes are also frequent; all the ordinary observing stations are supplied with seismographs, and shocks are recorded somewhere in the island about every day and a half. The most violent earthquakes are generally in the south-west, and occasionally cause disastrous damage.

ORNITHOLOGICAL NOTES.

THE eighth volume, comprising 533 pages of text, of the *Boletin do Museu Goeldi (Museu Paraense)* is devoted to a catalogue of the birds of Amazonia—Catalogo das Aves Amazonicas—by Dr. E. Snethlage. The author, who joined the staff of the museum at Para in 1905, commenced work on this catalogue very soon after his arrival, and devoted to it a large portion of his time during the following half-dozen years. Fortunately, the collection of bird-skins in the museum—some 10,000 in number—is sufficiently comprehensive to have enabled him to accomplish his task on a thoroughly scientific and first-hand basis. The result is a work which forms a worthy companion to Dr. Ridgway's "Birds of North and Middle America," albeit in an absolutely and relatively smaller compass. The author is, indeed, to be congratulated on the conciseness of the generic and specific diagnosis and the clearness of the "keys."

In connection with the above may be noticed the concluding portion of Mr. R. Dabbene's distributional list of Argentine birds, which appears in No. 6 of the first volume of the *Boletin de la Sociedad Physis,* Buenos Aires. The author recognises a total of 324 species. In Dr. Snethlage's catalogue the species are not numbered.

In an editorial article in the August issue of *Wild Life* it is stated that the Paris Committee of Economic Ornithology has been discussing a scheme for breeding white egrets in the marshes of Corsica, and also for rearing these and other birds with valuable plumage in Tunis. In the latter country the idea is that the Government should offer stock-birds on easy terms to the colonists, such birds to remain Government property, but the resulting offspring to belong to the breeders. The same issue contains two beautifully illustrated articles on Spanish heronries, where white egrets, night-herons, and other allied species breed in large colonies.

The July number of *The Emu* contains coloured illustrations of two species of parrots from Northern Queensland, severally representing genera unknown

to occur on the Australian mainland until last year. The first is a local race of Geoffroy's parrot (*Geoffroyus personatus* or *G. geoffroyi*) of Timor, and the second of the red-sided parrot (*Eclectus pectoralis*) of New Guinea. That such common and brilliantly coloured birds should have so long escaped detection in a country like Northern Queensland is very remarkable.

In an article on the ecological relations of bird-distribution, published in the July issue of *British Birds*, Mr. S. E. Brock remarks that while the composition of a country's avifauna is, in one sense, directly related to the present and former configuration of land-masses, the form of its dispersal within the area is immediately attributable to the environmental control. In other words, "the efficient causes of separation between bird-groups in this country are less geographical than ecological; the specific environment is the true 'faunal area.' The group of species attached to a specific habitat compose an association the units of which are primarily inter-related through the connecting link of a common environment."

As the result of a recent comprehensive inquiry, by the issue of circulars, Mr. H. G. Alexander is enabled to give, in the September issue of *British Birds*, a full account of the present status of the land-rail in the British Isles. Throughout the south and east of England, at least from Devonshire to Lincolnshire and inclusive of the south-east Midlands, this once abundant species no longer breeds regularly, although a few pairs nest annually in most counties. In South Wales, the West of England, the Midlands, and so far north as the Pennine Range and the Yorkshire moors, a general decrease in numbers, apparently of more recent date than that in the east and south, is now in progress; but in the Pennines and the districts west of the same no decided diminution is noticeable, landrails being still abundant throughout this area, except on the moors. Everywhere the birds are recorded as mainly frequenting grass or clover, and seldom cereals. Whether this was always the case, or whether they formerly nested in corn, has an important bearing on several of the theories which have been advanced to explain the diminution in the numbers of the species.

In the same issue is recorded the occurrence on May 6, 1914, of a pair of Rüppell's warbler (*Sylvia rueppelli*) at Baldslow, Hastings. This is the first British record of this rare east European species.

To the Transactions of the New Zealand Institute for 1913 (vol. xlvi) Prof. W. B. Benham contributes an article on the nomenclature of New Zealand birds, based on the *Reference List* of Mathews and Iredale.

Another article in the same volume, by Mr. H. Hill, gives the fullest account hitherto published of the history of the early discoveries of moa-remains in New Zealand, together with a discussion as to their geological age, and the probable date of extermination of these giant birds. Contrary to the now generally accepted view that moas were killed off by the Maoris within the last few centuries, the author affirms that these birds lived during the late Pleistocene—the epoch of intense volcanic action in New Zealand—and that they all perished suddenly as the result of such seismic disturbances and the emission of poisonous vapours long previous to the advent of the Maoris, or any other race, in the islands. Basing his views solely on the result of observations on the east coast, Mr. Hill proceeds to observe that none of the numerous moa-remains found in caverns show any evidence of having been touched by men or dogs; and he considers that when the great seismic cataclysm occurred all the birds rushed to the upland caves for refuge—where they were in many cases imprisoned by the fall of pumice in front of the entrance—while others perished in the open, choked by clouds of ashes or by noisome vapours; the remains of these latter being subsequently carried down to the lowlands by floods. No reference, it may be added, is made to the comparatively fresh condition of moa-remains in many districts, or to their alleged association with Maori camping-places and camp-fires.

In an article on birds observed last spring during a yachting cruise amid the Scottish islands, published in the August number of the *Scottish Naturalist*, the Duchess of Bedford directs attention to the vast numbers of fulmars snared at that season by the natives of St. Kilda, who bring them in by boat-loads. Such a practice, remarks her Grace, seems short-sighted on the part of people who depend largely upon these birds for a living; but, nevertheless, the fulmars still maintain their numbers. On the "Stack," which was also visited, the number of gannets has been estimated by one observer at 8000, and by a second at 50,000; a revised estimate is between 5000 and 6000.

R. L.

ENGINEERING AT THE BRITISH ASSOCIATION.

THE proceedings in Section G opened at Melbourne with a paper by Prof. Petavel on aviation research. The author described the results of recent experiments on the air resistance of various shaped bodies at different speeds, and also on the lifting power of planes of various shapes. This was followed by a paper on railways and motive power by Prof. Dalby, who showed a number of curves relating to the development and cost of working of British railways, and discussed briefly the relative advantages of steam and electric traction. Mr. Hedley Thomson followed with a paper on a transmission system suitable for heavy internal-combustion locomotives, in which he maintained that the difficulties of the internal-combustion locomotive were mainly due to the want of a suitable variable-speed control mechanism, and that these difficulties were overcome by the Thomas transmission gear, which he described. Curves were shown illustrating the high efficiency and other advantages to be obtained in this way. The internal-combustion locomotive is of special importance in Australia because of fuel and water difficulties. A paper was then read on the Canberra plan by Mr. W. B. Griffin, who was awarded the premium offered by the Commonwealth for the best town-planning scheme for the new Federal capital. The paper dealt with the principles underlying the design of such a town and their applications to the site at Canberra. The Government exhibited a number of elevations showing what Canberra will look like if and when the present scheme is carried through. The concluding paper on the first day was by Mr. Kirkpatrick, on the development of the Port of London.

On the second day Dr. Rosenhain read a paper on the behaviour of metals under strain, and showed a large number of photomicrographic slides illustrating the crystalline structure of metals under various conditions of strain and temperature. He showed that the various phenomena could be explained on Beilby's hypothesis of the amorphous phase in metals. Prof. Dalby then described an attachment for testing machines by means of which the stress-strain diagram is photographically recorded as the stress is applied. He also showed some photomicrographic slides of the structure of metals. A well-illustrated paper by Mr. Humphrey on the Humphrey pump was next read. The discussion showed that Australian engineers were fully alive to the importance of this pump for irrigation, but several speakers regretted the apparent de-

parture from its initial simplicity in order to meet special conditions. Prof. Coker read a paper on the stress distribution in short compression members. By means of a transparent specimen and polarised light, the peculiar stress distribution due to the compression plates being of different material from the specimen was illustrated. It was shown that approximately pure compression stress can be obtained if both are of the same material. Sir Oliver Lodge read a paper on the artificial electrification of the atmosphere, in which he dealt especially with the production of rain by the direct electrification of the clouds. The proposal was adversely criticised by Dr. Simpson, of the Indian Meteorological Department, and by Mr. Hunt, the Commonwealth Meteorologist. It was pointed out that clouds are very poor conductors, hence the difficulty of giving them an electric charge, and, moreover, that the clouds are often very highly charged, as shown by lightning discharges, and yet without causing rain.

The third day was devoted to a joint discussion with the Agricultural Section on irrigation, opened by Prof. Luiggi, of Rome, with a very interesting paper on irrigation works in Italy. The author showed that irrigation and ceaseless toil had transformed large areas of arid land into smiling gardens. He went very fully into the financial aspect of the question, showing that irrigation schemes require Government support, and are not suitable for private enterprise. He described the engineering features of several of the large schemes now being developed in Italy. A paper on somewhat similar lines, entitled "Irrigation in Victoria," was read by Mr. J. H. Dethridge. Papers were read by Mr. Ferrar on the fertility of lower Egypt, and some factors controlling the growth of cotton.

The Sydney meeting opened with the presidential address on stress distribution in materials. The president, Prof. E. G. Coker, discussed the various experimental methods, dealing especially with two, viz., the measurement of local temperature rise due to strain, and the application of polarised light to transparent test-pieces. Mr. A. B. Wade read a paper on irrigation in New South Wales, in which, after discussing the rainfall and physiography of the State, he described the irrigation schemes now in hand, especially that in the Murrumbidgee area. He also described the construction of the great Burrinjuck dam. Prof. Luiggi showed a large number of lantern slides illustrating the works carried out under his direction in Tripoli since the Italian occupation; these include lighthouses, harbours, waterworks, railways, etc. He emphasised the fertility of a great part of the country, and pointed out that it was a great grain producer in the days of the Roman Empire, and that with irrigation and development it should once more become a prosperous agricultural country. Mr. T. W. Keele discussed the Nile flood records between A.D. 641 and A.D. 1451, in which he claims to have found a periodicity of seventy-six years and suggests a connection with Halley's comet. Prof. Dalby described the new engineering laboratories of the City and Guilds (Engineering) College, which are at present nearing completion.

On the second day Mr. Bradfield read a paper on the new electric metropolitan railway, for which Sydney is seeking Parliamentary sanction. The scheme includes a bridge of 1600 ft. span across the harbour, and the total estimated cost of the whole scheme is 17,000,000*l*. A paper was read by Mr. Adams on the Australian ports in relation to modern shipping, in which the author discusses the great demands made on the port authorities by the increased length and draught of modern ships and the consequent outlay which neutralises to some extent the saving effected by the increased capacity of the ships. The new wharf arrangements at Sydney were described.

Dr. Rosenhain followed with a paper on the distribution of phosphorus in steel, in which, after describing a new reagent (ferric chloride with small quantities of copper and tin chlorides) for tinting the surface and thus revealing the want of uniformity in the distribution of the phosphorus, he showed a number of photomicrographic slides. Prof. Hudson Beare described tests which he had made on two petrol fire-engines, and also on the resistance offered to the flow of water by canvas fire hose.

On the last day of the meeting Prof. E. G. Coker read a paper on the temperature cycle in heat engines, describing a method of obtaining records of the temperature cycles in gas-engine cylinders by means of thermo-junctions operating an Einthoven galvanometer. Prof. Thornton followed with a paper on the lost pressure in gaseous explosions, in which he suggested that the difference between the calculated and measured maximum pressure may be due to the sudden effect of the forces of cohesion in converting translational into rotational energy at the moment of formation of the molecule. A second paper was read by Prof. Thornton on the limiting conditions for the safe use of electricity in coal mining, in which he discussed the danger of explosion from electric sparks under various conditions. Mr. Balsillie contributed a paper describing the system of radio-telegraphy with which his name is identified, and which has been adopted by the Australian Government, the chief features of which are that electrostatic coupling is employed between the oscillatory circuit and the aerial, and that a gap is employed with a very powerful air-blast, which, it is claimed, gives a unidirectional spark and consequent quenching after a semi-period. In a paper on the capacity of radio-telegraphic aerials, Prof. G. W. O. Howe described a method of calculating rapidly the capacity of any type of aerial.

Two reports were presented by research committees; that by the committee on stress distributions in engineering materials consists mainly of a review and bibliography of the experimental methods of investigating the subject, especially the application of polarised light to transparent test-pieces. A number of the committee are engaged on work which is not yet completed. A stock of 3 tons of standard steel has been obtained so that all members may work on the same material and thus enable their results to be correlated.

The report of the committee on gaseous explosions summarises previous reports and discusses the measurement of the temperature in gas-engine cylinders, especially the method employed by Profs. Callendar and Dalby at the City and Guilds (Engineering) College.

A joint discussion between Sections A and G on wireless telegraphy was held at Sydney. Sir Oliver Lodge, who opened the discussion, reviewed the various explanations put forward to account for the transmission of signals around the curvature of the earth, and the variations due to the alternation of light and darkness. Mr. Balsillie, the Commonwealth wireless expert, communicated some very striking observations; he had found that with a wave-length of 600 metres the ranges by day and night were 450 and 2000 miles respectively, and that by increasing the wave-length the day-range was increased while the night-range remained unchanged. Enormous variations in the day-range were produced by small changes in the wave-length, *e.g.* from 600 to 800 metres. The long range at night was obtained equally well over land or sea, which suggested that the waves travelled through the upper atmosphere and not in proximity

to the earth. Prof. Howe showed curves indicating in some cases a marked maximum in the strength of signals at midnight, and not, as one might expect, a uniform strength during the whole period of darkness. Dr. Eccles related some remarkable effects noted in the neighbourhood of Pago-Pago, a very lofty pinnacle of highly insulating lava with a wireless station on the summit. A ship near the island received distant signals better when the island was in a position to intercept the waves, as if the lava pinnacle deflected the waves and concentrated them on the ship.

MALARIA AND THE TRANSMISSION OF DISEASES.[1]

WHEN I received the distinguished honour of being invited by the committee of this school to deliver the biennial Huxley Lecture—an honour depending not only on the merits of the school itself, but on the names of some of the greatest leaders of the profession who have actually delivered the lecture in the past—I conceived it to be my first duty to select a theme which might be worthy of the occasion. In that fine book, the "Historical Account of the Charing Cross Hospital and Medical School," by Dr. William Hunter, the eminent dean of the school, it is shown that the founder of the hospital and the school, Dr. Benjamin Golding, had already recognised so long ago as 1821 the importance of the study of tropical medicine; and it was therefore impossible that the subject of my lecture of to-day should not lie in this field. But the field is large; and I should be losing myself in the sand of too great diffusion were I even to attempt a cursory survey of it. It was told, however—and gathered from the lectures of my predecessors—that what my audience most desire to hear would be, not remarks upon others' findings, but rather a succinct history of personal experiences, displayed from the widest point of view. I say this to excuse my somewhat personal choice of theme. The history will be a survey of the past; and, though wider for that reason, may be the more lacking in interest to some of you who perhaps have already heard much of these combats of a day already bygone. It is the narrative of a very humble foot-soldier, but one, alas! who is no longer employed by his country at the front. My subject will be malaria and the transmission of diseases.

First allow me to add a little wreath to the monument which the past lecturers have erected to the memory of the great Huxley—and I should like to place it upon a vacant spot. We all know Huxley as the St. Paul of evolution, the bulldog of Darwin (as he described himself), and the interpreter of Darwin's profoundities to the world; and we also know him as the patient and passionate investigator and the patient and dispassionate thinker regarding phenomena. But, in my opinion, he was still more—though not a higher thing—a philosopher. Like thousands of others, I have been fed and refreshed with those wonderful essays, which, when, as his biographer tells us, his hand grew heavy for dissections, he gave to the world in his latter days. To my mind he had all of the very first qualities required for true philosophy. The clarity of his style, which he possessed in common with Hobbes, Locke, and Hume and the great French philosophers, was itself a guarantee of the genuineness and completeness of his thought—so different from the obscurity and pretension of style which many philosophers from the days of Herakleitus onwards have employed to cover their emptiness. Secondly, his mind was fiercely critical in its search for truth, and he accepted nothing as fact which he himself had not endeavoured to probe into to the depths. Thirdly, no one has ever doubted that his aim was, not to astonish or to defeat or to persuade, so much as to reach the actual truth of every matter which he dealt with; and this serves to distinguish him from many of those who work in a field which is particularly open to pretence and even to charlatanry. We all trust Huxley. He may have been wrong for want of facts, but not for want of sincerity and effort. It is the fashion of one generation to decry the labours of the preceding generation; but as time advances this error is put right, and Huxley will be seen from the distance to soar more and more above the eminent writers of his own time.

I can imagine nothing that would have delighted him more than the bearing of recent advances in science on the medicine of the tropics. Indeed, this latest victory of science, achieved after his time, may be considered as a culminating point in the practical application of science to the needs of suffering humanity. The victory has been won, not only by medicine, but by medicine and zoology fighting side by side—by those two great branches of science in which he himself was so proficient. Let me now describe the details of the campaign.

It is curious that though the transmission of disease is a matter of such vast import to every one of us, it has received so little investigation in the past. Even up to the middle of last century, our inquiries had led us little further than what I call the subscience of the subject—that is, we distinguished, classified, and named our various bodily inflictions. We also did more; for we had ascertained empirically the physiological and therapeutical effect of many drugs—quinine, opium, mercury, iodide of potassium, ipecacuanha, and others; and also that great genius Jenner had discovered a wonderful fact which is at the basis of the theory of immunity, prevention, and cure. But the causes of disease and their mode of transference still remained hidden. At that epoch, however, and afterwards, Pasteur, Koch, Lister, Behring, and others created the science of bacteriology. But still, though the information thus obtained was of prime importance to the pathologist, the physician, and the surgeon, we still remained much in the dark regarding one important issue, namely, the exact path of transmission of many diseases from man to man. Bacteria are easily saprophytic, and may have many paths of transmission, and, I fear, that we are still very much in doubt as to the most important of these numerous routes. We thought, and are often still inclined to think, that the germs of disease come to us from any place where they may be scattered—that they have not precise routes and points of entry. This leads us to a very vague prophylaxis. We undertake all kinds of disinfections in order to destroy the enemy, wherever he may possibly lurk; and the consequence is that we often fail to check infection as certainly as we wish. It has been the great result of the inquiries which I will now proceed to describe that they have, as the French say, precised our knowledge upon this point in connection with many diseases, and have indeed led to the discovery of another and most wonderful route of infection which until recently was undreamed of by the profession and the public.

The armies of science, like those of nations, commence with small beginnings and advance in parallel columns. If one column is checked by insuperable difficulties, the others endeavour to outflank the point of resistance; and a victory is often won by this means in science as in war. (Excuse my military similes, which appear to be appropriate at this hour.) That column of science which conquered the domain of bacteriology was brought to a standstill for some time as regards the exact transmission of disease until the

[1] The Huxley Lecture. Delivered at Charing Cross Hospital on Monday, November 2, by Sir Ronald Ross, K.C.B., F.R.S.

parallel column attacking from quite a different direction circumvented the difficulty in this respect.

The story commences with the studies of those obscure and often despised workers who toiled in the domains of parasitology. Some of the largest parasites were known in antiquity; but the ancients possessed quite a wrong notion of their origin, which they attributed to spontaneous generation—that is, they thought the parasites originate *de novo* in the host. In the seventeenth century, however, Radi proved that this hypothesis does not hold for certain insects; and later Pallas argued that parasites originate *ab ovo*, like other animals—that is, that their eggs escape from one host and enter another host, thus leading directly to the presence of parasites in the latter. This history possibly still holds for certain parasites; but in 1790 Abildgaard showed by experiments that some parasites of fish live not only in those fish, but for a part of their existence in certain water-fowl; and this extraordinary law, which may be called after De Barry's term slightly changed, the law of metaxeny, was proved during the middle of last century by Eschricht, Steenstrup, and especially Küchenmeister, to apply to a large number of Platodes and Cestodes. Afterwards Leuckart, Melnikoff, and others extended the law to cover other species, including species of Nematodes. A most important case was that of the *Filaria medinensis*, the famous guinea worm of man, which was shown by Fedschenko in 1869, following a suggestion of Leuckart, to be in common with man and a water flea (Cyclops). All this constituted a discovery which was both remarkable in that it exhibited the wonderful devices of nature for propagating parasites from host to host, and was also of the highest importance to mankind (though few recognised this point at the time) because it showed us how many of our great diseases are likely to be acquired.

Let me dwell on this point for a moment. Parasites, accustomed as they are to dwell in the safe retreats of certain portions of their host's body, must be exposed to great dangers whenever they come to pass, as they must do from one individual host to another. Thus if this passage is effected merely by the egg, it is obvious that the eggs must be poured out in immense numbers to compensate for their immense destruction outside the body of the host; since it would always be probable that only a very minute proportion of the eggs would ever find their way again into fresh hosts of the proper species. In order to avoid these difficulties, nature, I presume through an infinite period of evolution, has enabled many parasites to acquire a more safe and certain route of entry—through other animals which are associated frequently with their first species of host. Thus, for instance, a parasite of dogs and cats develops also in the dog-louse, and is therefore not scattered broadcast from the dog and the cat over the surface of the earth, but is retained alive in close proximity to the bodies of those animals. Remember that nature is as solicitous for parasites as for the higher animals which contain them. She thinks no more of man than of the minute germ which infests him. From her open hand fall innumerable species, and she endows them all with equal powers of looking after themselves and their own interests. It is not in the interest of parasites to be wasted abroad. It is in their interest to be brought again as quickly as possible to the host in which evolution has formed them to live—and that is why this wonderful law of metaxeny holds good. It must be remembered, of course, that no species of parasite should be allowed to develop in excessive numbers in the same individual host, because this would result in the death of the latter, and therefore also of the former. The parasite must therefore find some means of transference at some stage in its life-history; and that route must be the most expeditious possible. This most expeditious route will often be, as I have said, through another species of animal connected in its habits with the original host.

Following upon the discovery of Fedschenko, Manson in 1877 showed that the embryos of another Filaria of man (*Filaria bancrofti*) develop in a species of mosquito, probably a Culex. The life-cycle of this parasite, up to the point to which he demonstrated it, was closely similar to that demonstrated by Fedschenko for *F. medinensis*; and Manson did not complete the story. Now, however, other important discoveries were made, which showed that animal parasites do not by any means belong only to the zoological groups of the Cestodes, Platodes, and Nematodes, but that many of them are unicellular. Thus Leuckart established the protozoal order of the Sporozoa; Lankester and others discovered Trypanosomes and Hæmogregarines; Davaine discovered Cercomonads, and Lösch discovered the group of parasitic Amœbæ. Lastly, in 1890, Laveran made the most important discovery that malaria is associated with a minute protozoal parasite of the blood; and his observations were followed by those of Danilewski and others, who showed that similar parasites are to be found in many animals. All this extended the catalogue of animal parasites over a vastly larger field than was known to the ancients; and the morphology and life-history of the parasites in the known hosts were elaborated by numbers of workers, who also succeeded gradually in connecting them with some of the most important diseases which inflict man and animals. Thus it was gradually shown that Amœbæ are the cause of one form of dysentery and abscess of the liver; that Trypanosomes cause the deadly nagana of domestic animals in Africa, and the equally deadly sleeping sickness of man, besides many other maladies of animals of numbers of species. Ankylostomes were proved to cause miner's anæmia, which also was shown to be prevalent through vast areas of the tropics, by no means only among miners. The Trematodes called Bilharzia were shown to produce a terrible form of cystitis in Egypt and elsewhere. *F. bancrofti* were proved to produce elephantiasis and a number of other maladies which are very common in the tropics. Simultaneously malaria was seen to be caused by at least three different species of the group discovered by Laveran.

At the same time, of course, as I have said, the habits of all these parasites in the hosts in which they had been found were being minutely examined. But up to the last decade of last century we still could form scarcely any definite idea as to how the protozoal parasites pass from one individual host to another. The law of metaxeny which had been proved to apply to many of the larger parasites had not been extended to the smaller ones. In 1889, however, Smith and Kilborne discovered a small parasite called Piroplasma in the blood of cattle suffering from Texas fever; and, more than that, showed that in some mysterious way the infection is carried from ox to ox by means of certain cattle ticks—though they did not demonstrate in any way that these parasites undergo a metaxynous stage of development in the ticks, and indeed failed to find them at all in these arthropods. In 1896 also Bruce made his famous discovery that the Trypanosomes of nagana are conveyed by certain tsetse-flies, but supposed that the carriage is a mechanical one. And there the matter rested until the solution of the malaria problem opened a new field.

We now turn to the subject of malaria. Economically, as well as medically, it is certainly the most important disease in the tropics, perhaps in the world.

It is found almost everywhere in hot climates, and even in most temperate climates during the summer. From statistics we find that as a broad general rule in malarious countries about one-third of the total population suffers from attacks every year, and also that about one-third of the admissions to hospital and attendances at dispensaries are due to malaria. But these figures are merely based upon records, and do not cover the enormous additional number of patients who remain untreated. Thus we know that the malaria-parasites or malarial enlargement of the spleen can be found in native children in malarious countries to an enormous extent, reaching 100 per cent. in very insalubrious spots. The case mortality is only about 0·5 per cent., but the prevalence of the disease is so extremely great that the total mortality caused by it makes an addition to the general mortality of anything up to 10 per mille, or even 15 per mille; and the malady complicates all other diseases in the tropics in a way which renders them more difficult to treat. In India alone it has been officially estimated that the total deaths from malaria average about 1,300,000 a year in ordinary years, and may reach a much higher figure during years of epidemic prevalence. Thus the total bill of annual mortality and sickness which King Malaria presents to the human race is something enormous.

Hence the development of the human race, especially in warm countries, has long demanded that we should ascertain exactly how this plague is propagated and should endeavour to find how best it may be prevented. It is remarkable that even more than five hundred years before Christ the ancients certainly were acquainted with one great law, namely, that malaria is connected with stagnant water, such as marshes; and there are good grounds for believing that Empedokles of Sicily actually delivered Selinus from malaria by draining its marshes or by turning two rivers into them. This knowledge seems to have been generally held since ancient times, though it must have been acquired quite empirically; but Varro and Columella, at about the time of the Christian era, actually suggested that the disease is in some way connected with insects which breed in marshes. In more modern times, however, malaria has been ascribed to noxious vapours given off by stagnant collections of water—the hypothesis evidently being that the poison is some kind of chemical one. I have mentioned that in 1880 Laveran discovered that the disease is due to certain protozoal parasites in the blood. When this fact was accepted ten years later, many observers at once rushed to the conclusion that these parasites have an extra corporeal existence in marsh water, and actually attempted to demonstrate this by producing infection in healthy persons by such water brought from malarious localities. The experiments of Agenore Zeri (1890) are to be particularly mentioned. He gave water from the Pontine marshes persistently to a number of persons orally or in spray, or by clyster—but entirely without result. At the same time many thought that the poison may lie, not only in stagnant water, but generally in the soil of warm countries—this being called the hypothesis of the telluric miasma; but, of course, this was merely a hypothesis which did not rest upon any observations or experiments. Even ten years after Laveran's discovery we were still completely ignorant as to how the malaria parasites enter the body. We might search for them in marshes and soil; but the search was likely to prove extremely difficult, because all water and soil is full of innumerable different organisms, and it would have been no light task to ascertain which of all these are really responsible for the disease among men, especially since Zeri had shown how difficult it was to produce infection by means of water in bulk.

At the same time, however, the hypothesis originally but vaguely mooted by Varro and Columella had been gaining ground. Indeed, Lancisi had repeated the same speculation in 1717, and seems actually to have suspected mosquitoes and to have studied them. So late as 1881 several theorists repeated this conception, though on studying their statements I think that little value is to be attached to them. In 1883, however, Dr. A. F. A. King wrote a most able paper on the subject, in which he gives no fewer than nineteen reasons why mosquitoes are likely to carry malaria. He thought that the insects bring the poison from the marsh and inoculate it into men. Many of his reasons are good, but others are now seen to have been untenable—and, in any case, he gave no experimental evidence. Next year, Laveran himself and Robert Koch independently enunciated the same speculation, but gave few reasons and no experiments in support of it. Ten years later, however, Manson repeated the hypothesis, but in a different form. He depended less upon the epidemiological evidence cited by King than upon certain parasitological evidence which occurred to himself. By this time (1894) the parasites of malaria had been very carefully studied, and were shown to possess, not only certain forms which provide for their propagation in the human host, but also other forms which, when the blood is freshly drawn, emit several so-called flagellated bodies. These latter forms had really led Laveran to his discovery, but their zoological significance still remained quite unexplained, and while some writers thought that they had some special significance, others believed them to be merely the result of death *in vitro*. Manson now urged that the flagellated bodies given off from these forms are really flagellated spores; that when mosquitoes ingest blood containing these forms, the flagellated spores escape in the insect and enter its tissues, where they ripen into some further unknown stage. Then, he thought, the insect dies two or three days later on the surface of the water, and this later stage of the parasites enters the water, and finally rises in the marsh mist to infect man. Obviously therefore Manson's hypothesis was quite different from King's; the former thought that mosquitoes derived the parasite from men and transferred it to the marsh, while King though just the opposite. Neither really reached the wonderful truth: both were half right, both half wrong. One cited parasitological and the other epidemiological evidence; and neither attempted experimental verifications.

Nevertheless, all these hypotheses, including those of the telluric miasma, were necessary for the laborious experimental inquiry which was now evidently demanded in the supreme interests of human life and health. I gather from what I have been told that my own work on the subject may prove sufficiently interesting to students to be worthy of mention here. I was first drawn to the malaria problem in the year 1889, when I observed during active service in Burma that the prevalence of malaria did not at all accord with the theory of the telluric and marsh miasma; and my doubts were strengthened during subsequent years by careful thought and study. If the poison is given off in an aerial form either from water or from soil, the disease ought to be almost uniformly distributed. Such, however, is not the case, and it really occurs principally in very small spots or pockets, generally in close proximity to stagnant water. Thus in one station where I afterwards served, my regiment was severely inflicted, while other regiments, scarcely a mile distant, remained almost entirely free. I was therefore very dissatisfied with this hypothesis, and being acutely alive to the great importance of the problem, I determined to study it carefully. In 1894 Manson acquainted me with his hypothesis, and I then

remembered that Laveran had said the same thing; but I was not aware of King's paper, or of the remarkable researches on Piroplasma by Smith and Kilborne.

In 1895 I attacked the work experimentally at Secunderabad in India, and determined first to adopt the mosquito speculation as a working hypothesis, and then to study other hypotheses if it failed—though I was much impressed by the former. The whole history of my work has been fully given in my Nobel Lecture, published in England by the Journal of the Royal Army Medical Corps (1905); and I need mention here only the salient points. For more than two years I caused mosquitoes of the genera Culex and Stegomyia to feed on patients containing malaria "crescents," which were the proper forms for transmission according to Manson. But my failure was complete, and indeed it was impossible to follow what he thought were flagellated spores in the insect's tissues.

I then adopted another technique, which was to compare insects of the same species which had been fed on malarial blood with those which had not been so fed, and to see if I could find any particular parasites in the former after they had been kept alive for some days. Many hundreds of insects were studied completely in this manner, and more than a thousand incompletely; but my failure was still complete. I obtained, however, a close practical experience of the insect's tissues, and learnt much about some common parasites which they possess. I also endeavoured to infect healthy persons by means of water in which presumably infected mosquitoes had been allowed to die, as Manson thought that such water would infect; and, lastly, I worked at a hypothesis of mine, that infected mosquitoes might carry infection by their bites, and Mr. Appia, assistant-surgeon of my hospital at Bangalore, kindly submitted to be bitten by many such insects in 1896. The result still remained quite negative. We now know the reason: the species of insect with which I was working were the wrong species. In 1907, however, I observed another variety, which I called dappled-winged mosquitoes, and which everyone now knows were Anophelines. I first saw these in an intensely malarious quarter near Ootacamund, where I myself acquired malaria during my investigations. A few months later I obtained eight of these insects in Secunderabad, and employed them for my usual experiments. Six of them died or gave bad dissections.

On August 20, 1897, I was so fortunate as to find in the tissues of one of these insects, four days after it had been fed upon a case of malaria, certain bodies which I had never observed in mosquitoes before. These contained the characteristic pigment of the malaria parasite. Next day, August 21, I found the same bodies in the last mosquito of my batch of eight—only they were now larger and more definite. To those who had not worked at the subject, such evidence might appear slight indeed; to me, after years of toil and thought, the evidence was immensely strong. A little later I found the same bodies in two more mosquitoes, and knew that I was on the right track; I felt that the two unknown quantities of this complex equation had been simultaneously found—the species of mosquito which carries malaria, and the position which the parasites take in its tissues, namely, the wall of the intestine.

Now, after seventeen years, I may perhaps be allowed to mention this point in order to encourage those students who, as I was then, are toiling after the unknown. But I at least obtained success, not only by labour but also by supreme good fortune; and I believe that but for this good fortune on these dates, we should still have remained ignorant of the manner in which malaria is conveyed, and might have remained ignorant of it for the next century. Unfortunately my work was now interrupted for nearly six months, just at a point when I expected to unravel the whole history of the malaria parasites in a few weeks; and it was not until March of next year that I was able to take up the thread again in Calcutta. For many reasons I was then unable to work at the human parasites, but commenced the study of the malaria parasites of birds, which are closely similar to the former. In a very short time I was able to demonstrate the presence in mosquitoes of pigmented bodies derived from the allied parasites. These bodies were found to grow regularly during one week after the insects had been fed, to reach maturity, and to produce a number of elongated spores. Now came an intensely exciting moment. What happens to these spores? According to Manson's hypothesis, they ought to liberate themselves in the water in which the insects died; but I had now shown that the insects did not die after two or three days, as he supposed, but may live for weeks. I attempted to follow the spores in all directions through the insect's tissues, into the lower intestine, and even into the egg. On July 4, 1898, however, I observed the fact that the spores enter the insect's salivary or poison glands.

The full truth was now immediately disclosed, and proved to be far more wonderful than any of us had ever dreamed of. The parasites are not only taken from man by the mosquitoes, as Manson had supposed, and are not only put into man by the mosquitoes, as King had supposed, but both hypotheses are true, and the insect carries the parasites directly from man to man. Here then was merely another case of the great law of metaxeny, which, however, was now proved for the first time to hold good for protozoal parasites. The malaria, like many larger parasites, require two hosts for their life-cycle.

These researches mapped out step by step every detail of the transformation, and gave us a much greater logical certainty than could be obtained by isolated infection experiments. Nevertheless, such experiments were attempted immediately, and in July and August I infected twenty-two out of twenty-eight healthy birds by the means of the bites of infected Culex—thus completing the whole story in detail. True, that was done with birds' malaria, and I had only seen the first steps of the process with regard to human malaria; but, any zoologist will know that with such closely allied species, the life-cycle of one is sure to be almost exactly similar to the life-history of the other—as proved to be the case here. My work was now interrupted again, and for nearly a whole year; and it was not until August, 1899, that I was able to show directly that the human parasites have exactly the same development. Meantime, however, Koch and Daniels had confirmed my work on birds' malaria; and certain Italian workers repeated it with regard to the human parasites, even to causing infection in healthy human beings (November, 1898), three months after my similar work with birds.

A very important discovery had been meantime made quite independently by MacCallum and Opie in America (1897), who showed that the bodies which Manson had thought were flagellated spores, were really sperms. Thus the large pigmented cells which I had found in mosquitoes at the same date were really fertilised macrogametes. This gave a much more correct zoological interpretation to my phenomena; but did not otherwise disturb the history which I had ascertained.

This then was the result obtained. Let me summarise it briefly. From the time of the Romans, we were aware that the malarial fevers are connected

with marshes and stagnant water in warm countries. Later, when it was seen that the disease is not confined only to the proximity of marshes, the theorists conceived that there is a telluric poison which causes malaria, and is especially abundant in damp places. All this was a very general proposition; and in order to prevent the disease, it was necessary to undertake very extensive drainage. Now, however, the new knowledge obtained enabled us to particularise the exact route of infection. We believe no longer that the poison is spread uniformly in the air of warm countries, but know that it is always contained in the minute bodies of certain insects, and, more than that, in the still more minute salivary glands of those creatures. Here then, science had given us knowledge which could not fail to be of immense practical importance to the world.

The discovery of the full life-cycle of the parasites enables us, not only to exercise the route of infection, but to determine exactly which species of mosquitoes are concerned. My failures with numerous undetermined species of the genera Culex and Stegomyia had shown that these are probably innocuous as regards malaria; and my ultimate success with certain Anophelines had shown that these were inculpated. Since then, the work of many observers has proved that, out of about five hundred Culicidæ only about twenty species carry malaria, and that all these belong to the Anophelines. So that for the prevention of malaria we are not obliged to deal with mosquitoes in general, but only with particular species.

Still further, the knowledge so obtained enabled us to study exactly the habits of the culpable species. In fact, I necessarily began such studies during the whole of my researches. The genera Culex and Stegomyia breed most commonly in artificial collections of water round houses; but I saw as early as 1897 that the dappled-winged mosquitoes (Anophelines) breed principally in different sites; that is, chiefly in natural collections of water, such as marshes, puddles, streamlets, and the edges of lakes, ponds, and rivers. This had been known before in the case of certain species; but I now saw the great epidemiological and sanitary bearing of the phenomenon. The reason why malaria is connected with marshes was now fully established by quite independent work. Humanity had explained the fact by supposing that the poison of malaria itself rises from the marsh; it was now seen that it is not the poison itself that rises from the marsh but the carrier of the poison. The net result was the same, except that we now knew not only the source of the poison but the exact method of transference. After all, humanity had reached the truth by empirical observations made during thousands of years; but science, in confirming those observations, has brought them to a fine point of exact theory.

But these were by no means the only fruits obtained. To return to our military parallel, when a commanding position of the enemy is carried, victory extends to a large area round it. The principal function of men of science is not merely to observe, describe, and catalogue phenomena, but, above all, to solve difficult problems; and the solution of one such problem frequently gives us the solution of many more. Such has proved to be true also in this case; for so soon as we had solved the malaria problem we were able to apply the same theorem to a number of other diseases. As already stated, Manson had shown in 1879 that the embryos of *F. bancrofti* can live in certain species of Culex—but he had not shown how they pass back from these insects to man. Now, however, James and Low, working independently, showed that the embryos enter the insect's proboscis, thus suggesting that they return into the human circulation by a route similar to that which is used by the parasites of malaria, and this work has been well followed up by Bahr and many others.

Another discovery, concerned with one of the most important of human diseases, namely, yellow fever, was made by Reed, Carroll, Lazear, and Agramonte during the last days of last century. Without knowing the causative agent of that disease, they yet showed by direct experiments on human beings that the infection is carried directly from man to man by another species of mosquito, *Stegomyia fasciata*, or *calopus*. It had long been stated by epidemiologists that malaria differs from yellow fever in that the former is connected with damp and decaying vegetation and the latter with insanitary conditions round houses. The former hypothesis was verified by the observation that Anophelines breed in terrestrial waters, and the latter was now explained by the fact that Stegomyia breed in artificial collections of water round houses. A little later Graham gave strong evidence in favour of the theory that dengue fever is carried by a species of Culex.

Thus mosquitoes have now been incriminated as the carrying agents of no fewer than four important disease of man. But this is by no means all. I have mentioned that before my work Bruce incriminated *Glossina morsitans* as the carrying agent of nagana; and he and others now showed that the deadly sleeping sickness of Africa is carried by other tsetse-flies. Various Spirochætes, especially that of tick fever, have been shown to be conveyed by ticks. A peculiar type of comparatively mild fever of which the cause, like that of yellow fever, is still unknown, has been proved to be conveyed by sand-flies. Several diseases of animals have been proved to possess a similar history; and others, both of animals and men, are suspected to lie in the same category. Perhaps, however, the most important and dramatic result was that obtained in the case of plague—the most terrible of epidemic diseases, the wonder and the despair of humanity since the beginnings of history, the scourge which was so often attributed to the direct action of God. It is due really to the rat flea. And this discovery signals another advance, because plague is, as we all know, due, not to an animal, but a vegetable parasite; and we therefore see that bacteria also may adopt precise routes of entry. A similar case is that of Mediterranean fever, which is carried principally by the milk of infected goats; and leprosy (another supposed scourge of heaven) has been attributed to the bites of bed-bugs; while some are even beginning to think that measles is due to fleas.

Gentlemen, I have now completed my task. We have seen at least another instance of how strongly recent advances in science bear upon medicine—how they confirm facts previously guessed at, achieve victories formerly undreamed of, and establish great theorems which will be of value to humanity so long as civilisation exists. But they affect not only the theory and the treatment of disease, but, what is perhaps still more important, its prevention; and it is especially in this line that the new theorems affect us. A whole great epidemiological group of diseases has been separated out, the so-called insect-borne diseases, and they are perhaps on the whole the most important, at least in the tropics. But, more than that, these discoveries give us practical methods of prevention, which may be summed up in the two words—no vermin. We now have a great sanitary ideal put before us: so to manage our habitations, villages, towns, and cities that the vermin in them shall be reduced to the lowest possible figure. Scores of entomologists and medical men are now dealing exactly with the habits of these creatures and showing us how to effect the required object. It demands only intelli-

gence, energy, and organisation on the part of administrators. Unfortunately these qualities are not always forthcoming, and administration often lags years behind the dictates of science. Although fifteen years have now elapsed since many of the facts which I have described were discovered, I think that I may say after constant study of the subject, and with all due consideration, that mankind has hitherto not effected more than about one-tenth of the improvement of health which it might have effected already if it had put its heart into the business.

When I had completed my work in 1899 I had fondly dreamed that a few years would see the almost complete banishment of malaria from the principal towns and cities in the tropics; that those benign climates and those beautiful scenes would be almost rid at once of a scourge which has blighted them from time immemorial. In this I have been disappointed. True, much has been done in certain places, as in Panama, Ismailia, Italy, West Africa, and parts of India and the Malay States, and in some other spots; but much more might have been done had we remained fully alive to our opportunities—and our duties. It is not the fault of science that we do not fully utilise the gifts which she gives to us. None of us here will live to see the full fruition of those gifts in this particular case; but we have at least seen the beginning, and may believe that our children will reap the profit.

But it is ever thus with science. Her slaves are like labourers condemned to drive tunnels through mountains—working, perhaps for years, in darkness, and oppressed by the immense spissitudes of nature above them; but always encouraged by the hope that at any moment they may emerge into the sunlight and upon the vision of a new world. May I conclude, as appropriate to the subject of this address, with four lines which were written years ago by one who was then toiling at the researches here described and in the darkness of the most utter failure—at work, moreover, for which he had little liking or ambition. They may encourage others who are now in a like case. Writing generally of the sublime spirit of inquiry he said:—

Thee most we honour, thee
  Great Science. Hold thy way.
The end thou canst not see;
  But in the end, the day.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

EDINBURGH.—The election of the lord rector in each of the four Scottish Universities is one of the great events in a student's life. As a rule the candidates are chosen on account of their political eminence, and the election runs on purely party lines. For ten days preceding the election proper the Conservatives and Liberals vie with one another in the issue of posters, pamphlets, and cartoons. They raid each other's temporary offices at all hours of night and day; and in Edinburgh University when the great day of the election comes and the votes are being recorded in the various class-rooms, there is a gigantic tussle in the quadrangle so as to gain and hold a certain position of vantage below the clock. A torchlight procession finishes the day's doings. Early in the summer the two parties among the Edinburgh students chose Sir John Simon and Sir Edward Carson as their candidates, and had affairs developed normally there would have been very lively times. The shadow of the war, however, stayed the coming strife, and with great wisdom the leaders of the Liberal and Unionist Associations agreed to invite as their lord rector an eminent man of no political party. Their choice fell on Lord Kitchener, himself an honorary graduate of Edinburgh University. A new lord rector is chosen every three years. He represents the students on the University Court, the governing body of the University, and when present presides at the meetings of the Court. This, however, is a comparatively rare occurrence. His one imperative duty is to address the students of the University once during his tenure of office. The addresses of Lord Kitchener and of President Poincaré, who, as announced last week, has been elected rector of the University of Glasgow, will be looked forward to with great interest.

SHEFFIELD.—The council of the University has made the following appointments:—Mr. Wilfrid Vickers (Manchester), to the post of junior lecturer in education and assistant-master of method; Mr. H. J. Davies, to the post of demonstrator in engineering; and Mr. F. Orme, to the post of demonstrator in non-ferrous metallurgy.

The council of the University, realising that under the present exigencies of trade, manufacturers will be more than ever faced with problems requiring scientific solution, has approved the formation of a University Scientific Advisory Committee to offer assistance, under conditions arranged to safeguard the interests of the consulting profession, to manufacturers carrying on processes within the Sheffield University area. From applications already received, there is undoubtedly a big field for work in front of the committee.

MR. WINSTON CHURCHILL has been unanimously adopted as candidate for the rectorship of the University of Aberdeen, and will be returned unopposed on November 7.

A COURSE of six lectures on chemistry, beginning on November 16, is to be given at the Royal Academy of Arts, by Prof. A. P. Laurie, professor of chemistry in the academy. The lectures will be given on Mondays, Wednesdays, and Fridays, at 4 p.m. The subject of the first lecture will be the present condition and the pigments and mediums used in painting the Royal Academy diploma pictures. Future lectures will deal with modern pigments, mediums, oils, varnishes, methods of wall painting, the theory of colour, and the chemistry of building materials.

THE "Professional Classes War Relief Council" has issued an appeal for funds. Representatives from the chief professional institutions with representatives of the principal societies organising relief have united to form the council, so that it is acquainted with the circumstances and needs of each profession. The intention is to assist by advice and indirect help rather than by monetary assistance. The council does not intend to interfere in any way with the work of the committees controlling the various benevolent funds, but it thinks that considerable advantages will flow from bringing into close touch the professional institutions and the societies organising relief. The council will also be able to organise special kinds of assistance which will cause those funds to go further and do more ultimate good than would be possible without co-operation. The main object will be to bridge over the temporary difficulty caused by the war and to pave the way to permanent profitable employment. Since there is no other organisation or general fund to meet this kind of distress, the need for such a fund is very great. The chief forms of assistance arranged are in matters of education, training, emigration, maternity aid, and temporary employment, all of which are to be worked under separate representative subcommittees of men and women whose capabilities fit them especially for dealing with their special departments. It is necessary to form a central fund to carry on the work, this fund being used to maintain the forms of assistance

proposed; to help those members of professions which have no benevolent funds; to provide assistance for the families of professional men who have given up all to enlist for the service of their country. All those who have this need at heart are invited to send donations to the treasurer, Professional Classes War Relief Council, 13 and 14, Prince's Gate, S.W. Cheques to be crossed Messrs. Coutts and Co.

SOCIETIES AND ACADEMIES.

LONDON.

Zoological Society, October 27.—Prof. E. A. Minchin, vice-president, in the chair.—E. **Heron-Allen** and A. **Earland**: Foraminifera of the Kerimba Archipelago, obtained by Dr. J. J. Simpson in the years 1907–8. The area is new so far as the Foraminifera are concerned, the only records in any way approximating to it being the species described by d'Orbigny in 1826, by Brady in 1876 and 1884, by Möbius in 1880, and by Egger in 1893, from material which was collected from adjacent areas to the east of Madagascar, and off Mauritius and the Seychelles. The material consisted of fine siftings from dredgings, and having but few molluscan fragments and stones the larger adherent forms are poorly represented, but 470 species and varieties have been identified, including two new genera, and twenty-eight new species and varieties. The general facies is strikingly similar to that characteristic of Australian, Torres Straits, and Malay gatherings. The problem of distribution thus raised is obscure, the intervening ocean being abyssal, while the species now recorded are all shallow-water types. Many of the specialised forms common to these widely separated areas do not apparently occur in similar dredgings from intervening coasts, such as the Red and Arabian Seas. No doubt the equatorial current, which traverses the Indian Ocean from E. to W. and impinges on the African coast in our area, is primarily responsible for this phenomenon.—T. H. **Withers**: A new Cirripede. The description was based on a number of disconnected valves from the Chalk of Surrey and a complete specimen from the Chalk of Hertfordshire. Except for three valves referred to a new species of *Scalpellum* (*sensu lato*), the whole of the material belongs to a remarkable new asymmetrical Cirripede which differs from Verruca in the more primitive structure of the valves, in the presence of two lower lateral valves on the rostro-carinal side, and in the absence of interlocking ribs. This species represents the ancestral type from which has arisen the recent group of asymmetrical sessile Cirripedes forming the family Verrucidæ, and in its structure clearly shows its origin from the symmetrical pedunculate Cirripedes of the family Pollicipedidæ. It presents further evidence that the sessile condition was arrived at independently on several different lines of descent during the evolution of the Cirripedia.—W. L. **Distant**: Report on the Rhynchota collected by the Wollaston Expedition in Dutch New Guinea.

Challenger Society, October 28.—Dr. S. F. Harmer in the chair.—Dr. E. J. **Allen**: The artificial culture of marine plankton diatoms. Experiments were described in which it was attempted to grow cultures of the diatom *Thalassiosira gravida* in a medium containing only pure chemical salts dissolved in doubly distilled water, the medium having a composition as nearly as possible that of natural sea-water, with the addition of Miquel's nutrient solutions. In such purely artificial solutions little growth took place, but if a small percentage, even less than 1 per cent., of natural sea-water were added, large and vigorous cultures were obtained. There are reasons for supposing that this is due to the presence in the natural sea-water of minute traces of an organic substance which acts as a growth-stimulant. Provided that the small percentage of natural sea-water be present, the amounts of the various salts constituting the artificial sea-water, as well as the total salinity of the mixture, can be varied within wide limits without much detriment to the cultures.

MANCHESTER.

Literary and Philosophical Society, October 6.—Mr. Francis Nicholson, president, in the chair.—R. L. **Taylor** and Prof. Haldane **Gee**: Some original pen-and-ink diagrams used by Dalton. The uncertainty in Dalton's mind as to the number of atoms present in water, ammonia, carbon dioxide, and other compounds is faithfully reflected in some of the diagrams, and his attempts to depict the constitution of these and more complex bodies are full of interest.

October 20.—Mr. Francis Nicholson, president, in the chair.—Prof. S. J. **Hickson**: Sea-pens from the Malay Archipelago.—Dr. J. Stuart **Thomson**: Sea-pens from the Cape of Good Hope. These Pennatulaceæ were dredged off the coast of South Africa by the Cape Government trawler *Pieter Faure* during the ten years 1898–1907. Numerous species of scientific interest were collected, amongst which was *Cephalodiscus gilchristi*, an invertebrate having affinities with vertebrates. The collection of South African sea-pens is interesting, not so much because of the discovery of new species as on account of the fact that variations in certain species have been found which link genera together. One fine phosphorescent form, *Anthoptilum grandiflorum*, grows four or five feet in height, and is of a brick-red colour. It occurs in abundance at certain localities, probably forming dense miniature forests on the sea floor. The marine fauna of South Africa may be described as cosmopolitan in character.

PARIS.

Academy of Sciences, October 19.—M. P. Appell in the chair.—Gaston **Darboux**: A proposition relating to linear differential equations of the second order with two independent variables.—Pierre **Duhem**: The hydrodynamical paradox of Dalembert.—Edouard **Heckel**: Male castration of the giant maize of Serbia.—Comàs **Solà**: Photographic observation of a comet. The comet was found by its record on a photographic plate exposed October 17. It is probably identical with the comet discovered by Lunt at the Cape of Good Hope on September 18.—Ernest **Lebon**: A new table of divisors.—Alfred **Angot**: The earthquake of October 3, 1914. From the seismograph installed at the Parc Saint-Maur Observatory the epicentre was calculated to be 2600 kilometres distant, in Asia Minor. The epicentre proved to be only 150 kilometres from the calculated spot.

THE PLACE OF SCIENCE IN INDUSTRY.

AN interesting article, by Mr. W. H. Dawson, appears in the November number of the *Fortnightly Review*, under the heading "The Campaign against German Trade." It is there given as the opinion of one of "the six best known industrial leaders of Germany" that "England's days as an industrial country are over. Your industry will pass more and more into the hands of the younger nations, and you will become simply a trading country." The author of the article goes on to point out that the lesson of Germany's success will not be learned "if we refuse to grasp the fact that its people have brought to industrial and trading pursuits just the same habits of method, thoroughness, concentration, and seriousness which mark them in other departments of life." He attributes the success largely to the co-operation between science and industry which prevails in Germany. This cannot be denied; but a further reason for Germany's rivalry, so far as it is successful, is afforded by a quotation from a speech made in July, 1912, by the Prussian Minister of Commerce; it is that the desire of manufacturers is, without exception, that the import duties on competitive articles may be kept as high as possible, and the foreign duties on articles exported from Germany as low as possible. It is also emphasised by the writer of the article that German employers have never had to encounter systematic opposition on the part of the workers, as has so often been the case in this country. Again, the German cultivates methods of distribution much more sedulously than does the Englishman; he never forgets that he exists for his customers; and the larger firms, or combinations of them, keep highly paid agents in every important market. The Germans are also greatly aided by their banks, which advance money on the security of orders.

Mr. Dawson does not believe that changes in fiscal regulations alone would put the British manufacturers in the same favourable position as the German, although he does not deny the advantages of a protective tariff. British trade must be supported by foundations of brains, science, and education, if it is to succeed.

While the truth of the general scope of the article, of which an abstract has been given, cannot be denied, it appears doubtful whether British manufacturers would care to adopt all the methods of their competitors. The colour trade, to take an example, has been secured for Germany, not entirely by the training of the chemists and operatives, but by what the Germans somewhat indefinitely call "Kultur"—careful organisation. First, the management consists, not in a board of well-meaning elderly gentlemen with a works-manager in their employment, but in a board of specialists, whose business in life is to manage the factory, financially, chemically, and as engineers, and who are very highly paid for their services. Second, these gentlemen and a special staff are continuously on the look-out for any scientific discovery or invention (generally made in countries other than Germany) which can prove of advantage to their business. Third, a very large staff of men, trained in universities or in technical schools, is turned on to the problem of making such a discovery commercial, whether by securing cheap raw material, cheapening the process of manufacture, or creating a public demand for the article to be manufactured. Fourth, a legal staff is maintained, whose business it is to protect by patent all improvements, however apparently trivial, and to describe them so vaguely as to conceal them from their competitors; also to advise on means to crush competitors by expensive legal actions. Fifth, such companies are so powerful, that they can influence the central Government to protect all new developments, whether by imposing duties on articles which might possibly compete, by extending bounties to all exported products, or by securing advantages in freights to the coast, and in shipping the goods abroad. These gentlemen in some cases (not in all) have also to advise whether piracy is likely to be successful; whether it may not be possible, by infringing a patent, so to saddle an opponent with legal expenses as to break his competition. Sixth and last, agencies are maintained all over the world whereby the article is introduced to the notice of foreign purchasers, and an extensive credit system is encouraged.

Trade, in fact, is regarded in Germany as a war, in which all means of conquest are permissible. We are at present discovering, in the military operations of the Germans, the precise equivalent in war of their operations in trade. It remains to be seen whether we shall care to do business with them when a state of industry succeeds a state of war. If we are to conquer, we have the alternatives; to copy their methods; or to refuse to deal with them. Perhaps these

are not exclusive; for there are many things in their methods which we might with advantage copy; and we could perhaps boycott trade conducted according to plans which we consider dishonourable or underhand. Time alone will show. But this is a fitting opportunity to consider our position; and by organisation, by co-operation among our manufacturers rather than by competition between them, and by education in science of our directors and employees, we might do much to forestall the attack which will undoubtedly again be made on our commercial position, if, at the end of the war, any prospect of recuperation is left to Germany. WILLIAM RAMSAY.

SCIENCE THE HANDMAID OF ART.

The Pigments and Mediums of the Old Masters. By Prof. A. P. Laurie. Pp. xiv + 192 + xxxiv plates. (London: Macmillan and Co., Ltd., 1913.) Price 8*s*. 6*d*. net.

THE information given in this book shows that the scientific man has come to the aid of the art expert in his endeavour to determine the period and the authorship of paintings of disputed origin. The author's previous works on "Greek and Roman Methods of Painting" and on "Materials of the Painter's Craft" indicate in what degree historical and literary research coupled with technical knowledge can be relied upon as guides in such an inquiry.

The present volume shows to what extent exact experimental investigation can be utilised to assist in this matter. The methods available are based upon an examination of the physical and chemical properties of the pigments and mediums used, and a microscopical examination of the nature of the brush work of the picture. The latter has given very interesting results, and shows that great individuality is found in the work of different artists.

The method recommended by the author for a critical examination of the brush work is to make a photomicrographic reproduction of a selected portion of the picture under a magnification of about three diameters.

The author is gradually accumulating a series of such photomicrographs, of well-authenticated pictures, and these will certainly be a valuable aid in the detection of forgeries, copies, etc. Some striking plates are shown in the book illustrating the use of such brush work enlargements, and the value of the method is well seen by a comparison of plates vi. and vii.—the former from a picture by J. A. Watteau and the latter from a copy by a good modern artist.

In addition to their use for the purpose of identification, it appears probable that such photomicrographs might be of much value for instructional purposes, as indicating the methods adopted by noted artists in developing their effects.

The first ten chapters of the book deal with the examination of the pigments and mediums. The physical character of the pigments, such as coarseness of particles, simple or mixed character, etc., may be frequently determined *in situ* under a magnification of about 100 diameters; but the removal of a minute fragment of pigment for more detailed examination is usually desirable. This may be done by making use of a microscopic gouge about a millimetre in diameter, or a complete section through the picture may be obtained by using a hypodermic needle. Full instructions are given for the transference and examination of the fragments of pigment, all tests, of course, being applied under the microscope.

The identification of the pigments and medium used in well authenticated pictures, coupled with historical information regarding the nature of the pigments in use at certain periods, makes it possible approximately to date many pictures, and the knowledge of the particular palette used by an artist, together with an examination of his brushwork, greatly facilitates a judgment in cases of doubtful authenticity.

The book is thus of much interest, not only to dealer and collector, but to the artist and historian. It is obvious, however, that the new methods of examination should be applied to valuable works of art only by such special experts as Prof. Laurie, and there is some slight danger involved in the publication of methods of sampling "old masters," even when the sample is to be taken with a hypodermic needle.

WALTER M. GARDNER.

PUBLIC HEALTH.

(1) *Preliminary Report on the Treatment of Pulmonary Tuberculosis with Tuberculin.* By Dr. Noel D. Bardswell. With a Prefatory Note by Prof. Karl Pearson. Pp. xxi + 141. (London: H. K. Lewis, 1914.) Price 6*s*. net.

(2) *Cambridge Public Health Series. Isolation Hospitals.* By Dr. H. Franklin Parsons. Pp. xiv+275. (Cambridge: University Press, 1914.) Price 12*s*. 6*d*. net.

(3) *The Bacteriological Examination of Food and Water.* By Dr. William G. Savage. Pp. x+173. (Cambridge: University Press, 1914.) Price 7*s*. 6*d*. net.

(1) TREATMENT of tuberculosis, and in particular pulmonary tuberculosis (phthisis or consumption), with tuberculin is undoubtedly tending to increase in England, and a number of

sanitary authorities have established "tuberculin dispensaries," where it may be applied to the poorer population under adequate medical supervision. On the other hand many Continental authorities view tuberculin treatment with considerable distrust. The appearance of Dr. Bardswell's report is therefore opportune, and we could have hoped that experience in the King Edward VII. sanatorium might have settled the real value or otherwise of tuberculin in the treatment of consumption. Some of the data obtained seem to be in favour of it, but Prof. Karl Pearson has examined the statistical data, and concludes that they do not show "that obvious and marked advantage of tuberculin treatment which would raise it at once above all suspicion of showing what advantage it does show, owing to selection of patients. Correction for selection may show it with a slight credit or an actual debit. . . . When all selected cases are treated as at present, we shall have no suitable control to determine whether the treatment has any real value, unless indeed we again leave it off." We notice that X-ray photographs do not appear to be a routine method of examination at this sanatorium, which is surprising, and Spengler's picrin method for staining the tubercle bacillus might be adopted with advantage.

(2) This book on isolation hospitals must be regarded as an authoritative one, as Dr. Parsons was a recognised authority on the subject. The past tense is used because the author did not live to see the work through the press, and its correction and completion was undertaken by Dr. Bruce Low. The book contains far more than its title indicates, as it really deals with the whole question of isolation for the preventive treatment of infective diseases. Thus in addition to isolation hospitals, the subjects of home isolation, eucalyptus treatment, and the law in relation to infectious diseases are fully discussed. Under isolation hospitals, the subjects of area, site, design, staffing, removal and discharge of patients, and cost are dealt with. Additional chapters are devoted to the hospital system of the Metropolitan Asylums Board and sanatoria for tuberculosis. A number of plans with descriptions of existing isolation hospitals complete the work, which should be of the greatest value to public health students and authorities.

(3) Dr. Savage has brought together into one volume a mass of valuable data relating to the bacteriology of foods, water, air, soil, and sewage, together with a description of the methods employed for examining them bacteriologically. He himself has contributed much to the subject, and is therefore able to discuss critically the value of the various methods employed, and of the data obtained therefrom. In a final chapter the determination of antiseptic and germicidal power is described, and the composition of the media employed is given in an appendix. The book is a very useful addition to the Cambridge Public Health Series, which is now being issued under the editorship of Dr. Graham Smith and Mr. Purvis. R. T. HEWLETT.

LIGHT AND ITS ACTIONS.

(1) *Photo-Chemistry.* By Dr. S. E. Sheppard. Pp. x+461. (London: Longmans, Green and Co., 1914.) Price 12*s.* 6*d.*

(2) *Photo-Electricity.* By Prof. A. Ll. Hughes. Pp. viii+144. (Cambridge: University Press, 1914.) Price 6*s.* net.

THE interest of scientific workers in the chemical and physical changes brought about by light is shown by the number of works recently published bearing on this subject. The importance of investigations on the action of light can scarcely be over-estimated, seeing that human life is dependent on "that branch of applied photochemistry which is termed agriculture."

(1) Dr. Sheppard gives an account of the principal facts relating to photo-chemistry, and discusses the present state of the theory of the subject. The book is very unequal. So far as the facts are concerned, the description is generally clear, but in the more theoretical portions the author frequently runs amok and indulges in quasi-philosophical discussions which do not add to the lucidity of his argument. The work, unfortunately, justifies the complaints made against the literary style of many men of science. Thus on p. 229 we have a sentence containing fifteen lines, and on the following page a sentence of fourteen lines. The author has a predilection for the use of foreign words and for the introduction into his subject of new terms which are often only vaguely defined, if defined at all. We do not recognise "temps" as an English word, and do not regard *mass* and *measure* as interchangeable terms, though the author speaks of "Radiant Energy in Absolute Mass."

In spite of many faults of presentation the volume will be found useful, as it contains a large amount of matter not available in other English works. The first half of the book deals with the physical side of the subject, and includes chapters on the measurement of light quantities, the energetics of radiation, and the absorption of light. Actual light-sources are also considered, special attention being given to the light of the sun, either in its direct form or as diffused daylight. The mercury vapour lamp scarcely receives ade-

quate recognition. The second part of the book deals principally with the chemical changes due to different forms of radiation. The author summarises his views by saying: "The conception that in photo-chemical change singular intermediate complex ions, or, specifically speaking, veritable latent light-images, are formed, appears the most promising."

(2) The account of photo-electric phenomena given by Dr. Hughes is lucid and concise. The photo-electric effect is regarded as a form of ionisation by light. Most of our information as to such ionisation has been derived from a study of the action in the case of solids and liquids, owing to the fact that in the case of gases ionisation is only brought about by light of extremely short wave-lengths. The aim of the author appears to have been to give a comprehensive view of the present position of the subject. In this he has been successful, though the result is perhaps to mar the historical setting and to deny adequate recognition to some of the earlier workers. Thus the work of Hallwachs and his pupils on the influence of contact potential on photo-electric phenomena is not referred to. The "energy law" which is emphasised in this book was established mainly by the experiments of the author and of Richardson and Compton. It expresses the fact that the maximum emission energy of a photo-electron is a linear function of the frequency of the light. This is in accordance with the quantum theory of radiation developed by Planck and Einstein, and first applied by W. Wien (whose name is not mentioned) in connection with Röntgen rays in 1907.

Both volumes contain a subject index and an index of authors. In the case of the latter volume the index of authors is far from complete.

PHILOSOPHY.

(1) *A Theory of Civilisation.* By S. O. G. Douglas. Pp. 246. (London and Leipzig: T. Fisher Unwin, 1914.) Price 5*s*. net.

(2) *Our Knowledge of the External World, as a field for Scientific Method in Philosophy.* By B. Russell. Pp. vii+245. (London and Chicago: The Open Court Publishing Co., 1914.) Price 7*s*. 6*d*. net.

(1) A READABLE and well-informed treatment of civilisation viewed as the outcome of religious belief. The various "psychic illusions" are considered—Olympianism, Orphism, Christianity, Islam, Buddhism, the ancient religion of Peru, etc.—and it is argued that each religion has elements which tend to an advance in civilisation, these elements being always irrational, for the rational and critical and selfish elements furnish no driving power except as to the individual's own well-being. In course of time disillusionment comes about; the beliefs are gradually abandoned as the intellectual powers—which have grown with the civilisation—assert themselves critically, and there is then a slide down until civilisation and the general intelligence reach such a level of degeneracy that another "psychic illusion" becomes possible. The process then repeats itself; though the author apparently thinks that the crest of each civilisation-wave is, on the whole, higher than the last, the "spirit of evolution" selecting for each successive illusion that which will yield improved results. The interesting question naturally arises as to whether, after Christianity, we shall manage to get along without illusions at all, or whether a new illusion will impose itself, as before. The author inclines to the latter opinion, but wisely refrains from detailed prophecy.

(2) This volume contains Mr. Russell's Lowell Lectures, delivered in Boston last March and April. They deal with the various idealisms—Platonic, Berkeleyan, Bradleyan, etc.—as the title implies, but there is also some acute criticism of Bergson's intuitionism, and a full analysis of the old problems of Achilles and the tortoise, and the impossibility of the moving arrow's motion. The author maintains the fresh and brilliant yet easy style which always makes his writings a pleasure to read, and though, as he says, philosophy in becoming more scientific inevitably becomes less humanly interesting, it is likely to retain devotees as long as it has such exponents as Mr. Russell.

The book is, of course, mainly logical, and the modern position is maintained. "The trivial nonsense embodied in this [Aristotelian] tradition is still set in examinations, and defended by eminent authorities as an excellent 'propædeutic,' *i.e.* a training in those habits of solemn humbug which are so great a help in later life" (p. 33).

"The old logic put thought in fetters, while the new logic gives it wings. It has, in my opinion, introduced the same kind of advance into philosophy as Galileo introduced into physics, making it possible at last to see what kinds of problems may be capable of solution, and what kinds must be abandoned as beyond human powers. And where a solution appears possible, the new logic provides a method which enables us to obtain results that do not merely embody personal idiosyncrasies, but must command the assent of all who are competent to form an opinion" (p. 59).

BOTANY AND GARDENING.

(1) *The Standard Cyclopedia of Horticulture.* By L. H. Bailey. Vol. i, A. B. Pp. xx+602+plates. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1914.) 25*s.* net.

(2) *Plants and their Uses.* An Introduction to Botany. By F. S. Sargent. Pp. x+610. (London: Constable and Co., Ltd., 1914.) 5*s.* net.

(3) *My Garden in Summer.* By E. A. Bowles. Pp. viii+316+plates. (London and Edinburgh: S. C. and E. C. Jack, 1914.) 5*s.* net.

(4) *Some Desert Flowers collected near Cairo.* By Grace M. Crowfoot. Pp. 50 (35 plates). (Cairo: F. Diemer, n.d.) 6*s.*

(5) *Flower Favourites: Their Legends, Symbolism and Significance.* By Lizzie Deas. 2nd edition. Pp. viii+229. (London: Jarrold and Sons, n.d.). 3*s.* 6*d.* net.

(1) THE Standard Cyclopedia of Horticulture, by Mr. Bailey is indeed a monumental work—we wish that its weight did not add force to the use of our adjective. Only the first volume is before us, but from this it will be seen how comprehensive and useful the completed work will be. It is written from the point of view of the American horticulturist and in some respects is therefore not always suitable for the English reader, but so much is of real value to all engaged in the science that its decidedly American point of view does not detract seriously from its value to the British or Colonial reader.

An admirable synopsis of the plant kingdom extending over 78 pages, is followed by a very useful key to the families and genera of plants. Then comes an exhaustive list of plant names in Latin with their English equivalents, which should be found of great service. Our only quarrel with this portion is the division of the Latin words, as an aid to their pronunciation, but entirely irrespective of their formation. Surely the position of the accent would have been sufficient. How unpleasant and misleading are the following: *multíj ugus, oxyphýl lus, pentán drus, dichót omus,* and the like!

There is also a good glossary of terms.

The articles on the plants themselves are well written, and in addition there is a mass of general botanical information. Under the headings "Arboretum" and "Arboriculture," for instance, there is a disquisition of some 35 pages in double column, giving quite an exhaustive treatise on the subject. Plant weeding receives equally useful treatment. Some articles like that on flower arrangement might well have been omitted, but on the whole the book is a very useful publication, though had it been prepared for English readers they would probably have preferred a volume less discursive and more in the style of Nicholson's Dictionary.

(2) An old friend in a new dress presents certain attractions if the dress is suitable, but we object to a rather thin attempt to veil the usual form of teaching under a dull and useless cloak. Mr. Sargent sets out with the idea that botany can be best taught by approaching it from the economic side, and finds himself in difficulties because with each plant or group of plants he is in the midst of his subject before he has been able to deal with the elements. The earlier chapters which treat of plant foods, vegetables, fruits, spices, condiments, drugs, poisonous plants, etc., are very well done in their way, but the method necessarily results in a jumbling together of a heterogeneous collection of unrelated plants and masses of useful information set out in a dull and unattractive manner.

Then follows an account of certain natural orders, some treated diffusely, others very shortly, and a remarkable set of formulæ of seed plants which are fearsome to behold. We venture to think that he who seeks to derive a love of botany from Mr. Sargent's book will be in the unfortunate position of the blind man looking for the black hat.

(3) Why is it that so many people who excel in one sphere of life attempt to display their powers in directions in which they are quite unsuited? In the case of those who make books there are many sad examples of people who, however much they excel in their own particular line, are quite incapable of expressing with a pen what they can ordinarily impart with ease and grace by word of mouth. Among books dealing with gardens and gardening more than one case could be cited, but perhaps one of the most unfortunate efforts is that by Mr. Bowles in his attempt to describe his own beautiful garden. To those whose privilege it is to know the author, and who can appreciate his rare and intimate knowledge of plants and their cultural requirements, it is a matter of pain to find him in print a very Mr. Hyde by comparison.

If only he could have begun his chapters in the middle, and so obviated the terrible stumbling-block of a grandiloquent opening, things might have been better, but even in the middle of a chapter it is a severe trial to come across such a passage as this:

"Two out of our three bushes of *Buddleia globosa* reside close by where we now stand, and are providing free drinks for the bees and a de-

licious scent of heather-honey for my nose if I apply it to the golden cowslip-balls in miniature, after I have shaken off the bees, which might not behave kindly to my proboscis, mistaking it for a rival to their own in the honey-gathering trade."

This, alas! is typical of many others which give a painful stab in the middle of chapters containing a great deal of interesting and valuable information.

The book is illustrated by some very fair photographic reproductions, but the coloured plates are miserable. The sad part is that Mr. Bowles has the knowledge that others seek to acquire, but an evil spirit appears to haunt him when he takes his pen to write.

The book contains a great deal of very valuable and interesting information, but the shock to the literary sensibilities of those who seek to extract the gold is almost too severe.

(4) The pictures of desert flowers will be very useful to travellers interested in the desert flora of Egypt. The photographs, especially when taken in the field, are good, and the introductory twelve pages are well written. We hope Miss Crowfoot will be rewarded by a ready sale for her book, and induced thereby to publish a further volume of pictures of the flowers of the desert. Should this be feasible a plate giving a detailed study of the flowers, fruits, and leaves of each plant, would be a useful addition to accompany the plate showing the habit of the plant in its natural conditions.

(5) "Flower Favourites" is a very pretty little book, a storehouse of quaint legend and myth relating to some forty-eight well-known flowers. Among them are such familiar plants as the rose, cowslip, speedwell, leek, and hyacinth, and in all cases numerous quotations from the poets are given which refer to the particular flowers. It is a book for which lovers of flowers will be grateful, since it has been compiled with great care, and shows that the author has a very extensive knowledge of the ancient and modern literature of plant lore. It is essentially a book to be appreciated by those whose vision penetrates beneath the surface.

> "Earth's crammed with heaven
> And every common bush afire with God:
> But only he who sees takes off his shoes:
> The rest sit round and pluck the black berries.'

OUR BOOKSHELF.

Kinetische Stereochemie der Kohlenstoffverbindungen. By Dr. A. von Weinberg. Pp. viii+107. (Braunschweig: F. Vieweg und Sohn, 1914.) Price 3 marks.

IT would be difficult within the compass of a short notice to develop the highly speculative conception which underlies what the author terms "kinetische stereochemie." He claims that it will eliminate the vague notions which hover round the theory of valency, and have rendered it necessary to qualify this attribute by the use of "partial" valencies, broken valencies, distributed valencies, and valency electrons.

Dr. von Weinberg has attempted to prove that chemical changes are determined by atomic motions; that these motions are rotatory and vibratory, and are closely linked to the phenomena of heat of combustion and molecular refraction. He considers that by means of this conception it is possible to solve a variety of unsolved problems, such as the structure of benzene, the phenomenon of dynamic isomerism, the asymmetric carbon, optical activity and colour.

He lays down the proposition that in all states of aggregation the atom has motion, and that the energy content of these atomic motions in organic compounds may be determined by the atomic volumes, which in turn can be estimated as heat of combustion and atomic refractivity. He further assumes that singly-bound atoms rotate or oscillate round an axis, and that doubly- and treblylinked atoms undergo a vibratory movement. The difference in the heat of combustion of an atom when combined in an organic compound and when free as an elementary molecule is not a question of a change in chemical affinity, but of the increase or decrease in atomic motion in the two states. In the same way increase or decrease of atomic volume, as determined by the motion (rotatory or vibratory) of the combined atom, is manifested by the density of the liquid substance, *i.e.*, its refractivity. These two ideas are developed conjointly at some length, and a considerable mass of data is introduced to support the theory. We think that some of the statements are open to criticism, such, for example, as making one kind of atom in a compound responsible for the whole difference in the heat of combustion, and consequently in atomic motion and so forth. Whether these speculations, for they are pure speculations, will serve to stimulate further experimental inquiry is somewhat doubtful; but the theory is bold and suggestive, and the pamphlet is well worth perusal.

J. B. C.

The Essence of Astronomy: Things Everyone Should Know about the Sun, Moon, and Stars. By E. W. Price. Pp. xiv+207. (New York and London: G. P. Putnam's Sons, 1914.) Price 10s. 6d. net.

THE title "The Essence of Astronomy" gives a good idea of the lines on which this book has been written. The book does not pretend to be a treatise, and it deals only with the main, well-authenticated facts in a popular manner. All technical terms, mathematical formulæ, and symbols have been omitted in the text, but the last-mentioned are given on a separate page at the end of the volume.

Those who wish to read a simple and brief account of the main facts about the sun, planets, asteroids, comets, and stars (normal and abnormal) cannot do better than peruse this book. A general idea of the universe will be easily obtained, and some notion of the vast subject of astronomy will be gained. The illustrations are reproduced from some of the finest photographs ever taken, and they are well distributed and chosen. A brief bibliography of books more or less popular is given at the end; also a chronology of the main events of astronomy from very early times to 1908. With regard to the latter the author seems to think that such a table is unique or "what the compiler has never happened to see before." To take only one instance, he has evidently never seen Miss Clerke's admirable "History of Astronomy during the Nineteenth Century," at the end of which is a chronological table stating the main astronomical advances from 1774 to 1893.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Fizeau's Experiment and the Principle of Relativity.

MR. CUNNINGHAM seems determined that the principle of relativity shall assert supremacy as regards the Fizeau effect on the velocity of light, arising from motion of the transmitting medium. This is a first-order effect, while the principle of relativity was invented to account for the second order. Up to the first order the affairs of moving media hang entirely on the ascertained fundamental relations of electro-dynamics; and any type of relativity which does not agree with the formula thence deduced must, if substantiated, upset our whole system of ideas.

As regards the arguments adduced: (1) is of course a slip of the pen—he is thinking of steady viscous flow in a pipe, whereas the standard measures for ordinary turbulent flow are in general agreement with the values quoted from the experiment; while as regards (2), it seems certain that the experimenters must have had before them the effect of variation of velocity across the section of the pipe, which would curve the fronts of the waves and thus broaden the interference bands, but not much if only the central part of the pipe, in which the velocity varies but slightly, is employed. The shift at the centre of the band-system would depend on the axial velocity only.

JOSEPH LARMOR.

Cambridge, November 2.

THERE was no intention in the letter to which Sir Joseph Larmor refers (NATURE, October 29, p. 226) of suggesting that the principle of relativity and the fundamental relations of electro-dynamics were at variance with respect to this matter. Certainly I have always taken them to be completely at one. But it has been raised in several quarters as an objection to both points of view that the extremely careful experiment of Michelson and Morley was not in complete agreement with theory. They found the convection coefficient for water to be $0{\cdot}434 \pm 0{\cdot}02$, while theory (taking account of dispersion according to Lorentz's formula) gives $0{\cdot}451$, which is very near the limit of possible error.

Sir Joseph Larmor makes it clear that the suggestions which I made as to the possible origin of the discrepancy are untenable, and, I understand, feels that it must lie in the inherent difficulties of the experiment. One of these is the determination of the axial velocity in terms of the mean. The experimental device could not be expected, I think, to give a result correct to one or two per cent., inasmuch as the pressure gradient actually measured is partly the normal pressure gradient of the undisturbed flow, and partly that due to the disturbance produced by the insertion of the gauge-tubes.

But, as a matter of fact, the discrepancy is not so great as has been thought. A recalculation from the figures and formulæ of Michelson and Morley, which Sir Joseph Larmor has now checked for me, gives for the experimental value of the coefficient $0{\cdot}442$, with their estimated possible error of $\pm 0{\cdot}02$. Thus the discrepancy ($0{\cdot}009$) with the value given by Lorentz's formula (including dispersion) proves to be less than half the possible error.

E. CUNNINGHAM.

Wireless Signalling for Shipping in War Time.

THE advantage which wireless telegraphy has been in enabling the whereabouts of vessels at sea to be known from day to day, is now in abeyance, I believe, on account of the war, because of the messages being liable to be read by the enemy.

But if a system of signalling false latitudes and longitudes by a code prearranged by the owners, different for each craft, and variable from day to day, easy and simple to translate by reference to the copy kept, then wireless signalling could go on as freely as before, without danger of the code being captured by the capture of any craft.

To illustrate the method of this, let us suppose a firm of owners have two ships, the *Ariadne* and *Ocean Bird*. A list of dates has been given to each captain with instructions to falsify positions on the respective dates (London time) with additions and subtractions as found in the list in opposition to the dates, thus:—

SHIP "ARIADNE."

	Lat.	Long.
Nov. 1	$+14°$	$-21°$
2	$-16°$	$+15°$
3	$+30°$	$+20°$
etc.		

SHIP "OCEAN BIRD."

	Lat.	Long.
Nov. 1	$-18°$	$+24°$
2	$-16°$	$-21°$
3	$+18°$	$+15°$
etc.		

The owners of these ships could interpret the wireless messages received through the exchange, and the Admiralty be quickly notified of a disappearance with approximate latitude and longitude.

A. BOWMAN.

144 Well Street, Hackney.

NOTES ON STELLAR CLASSIFICATION.

IN all my early work at Kensington (1887) on the classification of stars according to their spectra, the best basis for a classification was chiefly considered. The data available were the chemical facts obtained by a detailed inquiry into the chemical origins of the various lines and flutings, using higher dispersion and more laboratory work than were employed in other observatories.

The first and most important result obtained was that it was found necessary to divide the stars into two groups, one set increasing their temperatures while in the other the temperature was running down.

This, indeed, added a *physical* difference to the chemical ones, and there was another, for on the meteoritic hypothesis the stars getting hotter were sparse swarms of meteorites being vaporised, while those getting colder were rapidly condensing into solid bodies.

These were fundamental changes of front. Up to that time only a line of decreasing temperature had been considered. Passing over the earlier classification of Rutherfurd (1863), which was only modified by Secchi (1867), though by those ignorant of the subject he is credited with the origination of it, I may mention that in 1873 I referred to the question of temperature in a Bakerian Lecture,[1] and in 1874 Vogel brought out a considerable classification. This was also based upon a line of descending temperatures. On this classification I wrote in another Bakerian Lecture (1882)[2]:—

"The idea which underlies the classification is that a star of Class I. on cooling becomes a star of Class II., and that a star of Class II. has as it were a choice before it of passing to Class III*a*. or Class III*b*. Thus under certain conditions its spectrum will take on the appearance of Secchi's third type, Class III*a*. (Vogel); in certain other conditions it will take on the appearance of Secchi's fourth type, Class III*b*. (Vogel). There is now, however, no doubt whatever that Secchi's Class III., represents stars in which the temperature is increasing, and with conditions not unlike those of the nebulæ—that is to say, the meteorites are discrete, and are on their way to form bodies of Class II. and Class I. by the ultimate vaporisation of all their meteoric constituents. There is also no doubt that the stars included in Class III*b*. have had their day; and that their temperature has been running down, until owing to reduction of temperature they are on the verge of invisibility brought about by the enormous absorption of carbon in their atmospheres."

"Pechüle was the first to object to Vogel's classification, mainly on the ground that Secchi's types III. and IV. had been improperly brought together; and my work has shown how very just his objection was, and how clear-sighted was his view as to the true position of stars of Class III*b*."

Prof. Keeler wrote in 1894[3] "Lockyer's system of stellar classification provides for both an ascending and a descending branch of the temperature curve, and in this respect it certainly has advantages over other systems which claim to have a rational basis."

Prof. Frost[4] thus alludes to it: "Many spectroscopists are unwilling to admit that the only course of stellar development is along a line of descending temperature." He does not name the "many spectroscopists," but he adds: "The further question may be raised—Is it not possible that a celestial body, after it has reached the condition in which we may define it as a star, may twice be red and exhibit a spectra of the third type, once in its youth and again in its old age?"

In my papers are many statements giving the answer to this question, years before Prof. Frost put it.

In the Bakerian Lecture (1888) I published a temperature curve with ascending and descending arms, along which stars could be arranged according to their swarm- and condensing-conditions and their temperature as revealed by the spectra. On it were rearranged stars as classified by Vogel and stars with bright lines and nebulæ. Another curve was given in the catalogue of 470 of the brighter stars which I afterwards published in 1902, in which I classified stars only, giving to each group a distinctive name.

Of the stellar spectra used, some had been photographed at the Solar Physics Observatory and others by Mr. McClean at the Cape and Tunbridge Wells.

A few years after the publication of Vogel's memoir the work of classification was taken up at Harvard. The first one adopted was an alphabetical, from A and B onwards in one line. This we may mark as H.1.

At about the same time (1888) that I published my temperature curve at Kensington, the classification of northern stellar spectra in special new groups was being carried on at Harvard by Miss Maury as part of the Henry Draper Memorial. The classification was on one line of temperature in groups numbered from i to xxii. (H.2.).

But Miss Maury did not content herself with the group classification; over and above her twenty-two groups of spectra she gave us three main divisions of stars depending upon the characteristics of the individual lines. Here we find a physical touch superadded. In Division *a* were included lines narrow and clear, in *b* lines relatively wide and hazy, and in *c*, among other conditions, unusually intense metallic but not solar lines. I found these divisions of the utmost value to me when I was preparing my classification.

The Southern stars were undertaken by Miss

[1] Phil. Trans., vol. clxiv., p. 292.
[2] Proc. R.S., vol. xliv., p. 1.
[3] "Ast. and Ast. Phys." 1894, p. 60.
[4] "Astronomical Spectroscopy," p. 318. 1894.

Cannon, who employed H.1., but some groups were discarded and stars between F and G, for instance, were classed as F5G or F8G. We may mark this as H.3.

The work of Harvard is monumental; tens of thousands of stars have been classified so far as small dispersion can do it, but obviously a straight line, instead of a curve of ascending and descending temperatures, has been followed in the three classifications used one after the other, and in all, if my views are sound, stars of vastly different constitution, sparse swarms and condensed stars, are called by the same name.

A subject of great regret is that, as this is the only large scale classification extant, it is now being used to deal with questions in which it is vital that stars differing in physical constitution shall *not* be classed together; in which such a mixing invalidates the conclusions arrived at in such inquiries.

In the last authoritative book published on these matters Prof. Eddington writes:—"From time to time there are indications that the Draper classification has not succeeded in separating the stars into really homogeneous groups. According to Sir Norman Lockyer there are stars of ascending temperature and of descending temperature in practically every group; so that, for example, the stars enumerated under K are a mixture of two classes, one in a very early, the other in a late stage of evolution."

Prof. Russell, a diligent worker on the characteristics and spectra of stars, has written as follows:—

"I have endeavoured . . . to set before you the present state of knowledge concerning the real brightness, masses, densities, temperatures and surface brightness of the stars, and to sketch the theory of stellar evolution to which the study of these things has led me. This theory is inconsistent with the generally accepted view. Its fundamental principle is identical with that of Lockyer's classification."

Prof. Russell objects to the principles on which I have placed stars in the different groups but that is another, and less important, story, which will be dealt with later.

Prof. Ludendorff[5] has recently provided a case in point; he has discussed Prof. Campbell's results on radial velocities and stellar types based upon the Harvard classification. Difficulties were met with. Dr. Ludendorff points out that these are avoided and that a distinct differentiation of the velocities is obtained if the stars are arranged in the order of ascending and descending temperatures. Of the sixty-three stars selected by Campbell, eighteen are contained in my classification; of these ten are on the ascending arm, and the velocities are all +; the remaining eight are on the descending arm, and the velocities, with one exception, are −. The exception is a star very near the top of the curve.

In arranging the programme of work for the Hill Observatory, the first place has been assigned to the continuation of the catalogue of the bright stars classified on my hypothesis (of two groups of stars, one increasing, the other decreasing their temperature), so that the 470 we already have may be as soon as possible increased to 1000, which will give us a broader base.

I have also occupied some time in considering stars varying from the normal condition dealt with in my published classification. These are:—

Stars with bright lines.

Variable stars with bright lines.

Variable stars without bright lines.

Double stars without bright lines.

The object of my inquiry was to ascertain whether further generalisations were suggested as regards the arm of the curve on which these stars should be most probably found, irrespective of their chemical constitution on which my classification was founded.

This further inquiry was based on my hypothesis[6] that the bright lines in variable stars were due to collisions between meteor swarms. Düner has shown that in Class III*a* (Antarian), of 297 stars 44 were variables, that is, 1 in 7. I found[7] in 1894 that in β Lyræ two bodies resembling Rigel and Bellatrix were involved. This lands us in the Crucian stage, nearly at the top of the ascending arm.

When we deal with variable stars without bright lines (eclipsing variables), the light curves show that we are dealing no longer with swarms, but with bodies with discs and therefore with photospheres, and therefore again approaching the solar condition. Now the best known variable of this class is Algol, the type star of one of my groups nearly at the top of the descending arm, nearly on a level with the Crucian group on the other.

From these facts we learn that bright line variables with the Harvard Classification, B. A. F. K. M. should be stars increasing their temperature, while eclipsing variables marked B. A. F. K. N. should be decreasing their temperature.

The result of the preliminary inquiries so far has been very encouraging.

Stars with bright lines have been found in species represented on the ascending arm of the curve, and none on the descending side.

All variable stars with bright lines so far studied belong to the ascending side, eclipsing stars which do not show bright lines to the descending arm.

A great majority of the double stars without bright lines so far considered belong to the descending arm.

Details on all these points will be given when the research is further advanced.

It may be remarked that the danger of using the Harvard classifications is not the same for all the groups.

The normal stars which differ most in their physical state are the Antarian (ascending) and the Piscian (descending). These are differentiated by the adjacent letters M and N (A and Z would have been better).

One of the finest memoirs which has ever been

[5] *Astronomische Nachrichten*, No. 4847, vol. cxc., p. 193.

written on stellar spectra is that of Düner on the two types, III*a*. and III*b*. of Vogel's classification. And a study of it will show that no two groups of spectra differ more widely than these.

To secure simplicity I represented the two arms of the temperature curve of equal inclination, and to save space I used a narrow angle between them (although by all analogy the descending arm should fall less rapidly than the ascending one). The more the curve is flattened the less difference there will be in the physical conditions of stars on either side of the apex representing the highest temperature. These stars, therefore, will be difficult to classify, and even some of the conditions may vary in the Alnitamian, Crucian, and Achernian groups.

It is half-way up the two curves that the greatest confusion may arise if stars of the same name; (A, F, K) are treated as if their physical state were similar, α Cygni and Sirius, for instance, both A in the Harvard classification (H.3). NORMAN LOCKYER.

(*To be continued.*)

THE SERVICE OF SCIENCE.

A FEW months ago public attention was being directed by articles and letters in the *Morning Post* to the inadequate remuneration and prospects of scientific workers, particularly those engaged in research. The subject is one to which many columns of NATURE have been devoted since the foundation of this journal in 1869, but it cannot be too widely discussed if any serious effort is to be made to secure improved conditions in the future. The present is not perhaps the most propitious moment to ask for increased endowment of science and encouragement of discovery, but there are points relating to the position of science which can be stated as appropriately now as at any time. Some of these matters are referred to in an article on "Science and the State" in the October number of *Science Progress*, and the whole subject is under consideration by a committee of the British Science Guild.

The article in *Science Progress* is in continuation of one which was published in the April number, and its purpose is to offer a programme of steps toward the betterment of science in Britain and elsewhere. It is shown that the emoluments of scientific men are much below what might reasonably be expected for exceptional attainments; and the claim is made that the State should offer special rewards or pensions to investigators whose researches have proved of decided national or public advantage without being profitable to themselves.

The unsatisfactory positions of many professors and lecturers in our universities and other institutions of higher education, is due largely to the management of the institutions by commercial men who like to see fine buildings but are unable to understand the use of most of the work carried on in them. It comes as a surprise to such men to be told that in scientific circles usefulness is rarely adopted as the standard of value; and that even if not a single practical result is reached by an investigation, the work is worth doing if it enlarges knowledge or increases our outlook upon the universe. This proposition, of course, leaves the practical man cold; yet it is all that science desires to offer in justification of its activities. While the discovery of truth remains its single aim, science is free to pursue inquiries in whatever direction it pleases; but when it permits itself to be dominated by the spirit of productive application it will become merely the galley-slave of short-sighted commerce. Almost all the investigations upon which modern industry has been built would have been crushed at the outset if immediate practical value had determined what work should be undertaken. Science brings back new seeds from the regions it explores, and they seem to be nothing but trivial curiosities to the people who look for profit from research, yet from these seeds come the mighty trees under which civilised man has his tent, while from the fruit he gains comfort and riches.

Industrial research is concerned, not with the discovery of truth, but with the production of something which will be of direct service to man and from which pecuniary profit may be secured: it is the province of the inventor rather than that of the man of science. Such research and that carried on with no ulterior motive are complementary to one another. Science has done its part when it has made a new discovery; constructive engineering renders good service when it shows how the discovery may be chained to the advancing chariot of industry. To foresee the possibilities of a discovery, to transform a laboratory experiment into the mechanical plant of a large works, or to apply it to the needs of ordinary life, require aptitudes not commonly possessed by the scientific investigator. The engineer usually has such practical purposes in mind; discoveries are to him things to be used and not ends in themselves, as they are to the man of science. He seeks not so much to know Nature as to circumvent her; and the research which he undertakes or organises has for its object the artificial preparation of substances which are naturally rare, the production of a new process or the improvement of an old, the design of machines which will increase his power over her, and of instruments which will enable him to laugh at limitations of time and space.

Research is necessary for these advances, but the spirit in which it is carried on is essentially different from that of the scientific worker. The engineer or the inventor first of all perceives a need and then endeavours to devise a means of meeting it. If he is of a scientific type of mind he will make an accurate analysis of the conditions to be fulfilled, and then design his machine or instrument to fulfil them; but the usual way is to find practically what will perform the required functions, and to leave experience or scientific knowledge to indicate how improvements may be effected.

Scientific research may thus be divided conveniently into two classes—one in which the motive is solely the desire to extend the boundaries of knowledge, while in the other the special purpose is to obtain results which have a direct bearing upon problems of manufacture and construction. Explorers on the ship of science go out to discover new lands; and their spirit is not the same as that which actuates the prospectors who follow them with the intention of making the lands profitable to themselves and others. Both these classes of pioneers have their proper places in the scheme of progress, but they live in different atmospheres. The scientific investigator must have freedom to follow his own course wherever it may lead, whereas technical research can be organised and definite problems presented for which solutions of direct service to man are sought. The standard of value in one case is that of knowledge only, while in the other it is that of profit or use. The scientific mind desires to understand Nature; the engineering mind to control her for material purposes.

Some time ago the votes of the readers of an American periodical—*Popular Mechanics*—were taken as to what inventions were considered to be the "seven wonders of the modern world." From a list of numerous inventions, seven had to be selected; and those which received the highest number of votes were: wireless telegraphy, the telephone, the aeroplane, radium, antiseptics and antitoxins, spectrum analysis, and X-rays. Each one of these things had its foundations in purely scientific work, and was not the result of deliberate intention to make something of service to humanity.

It would be easy to give many further instances of the foundation of great industries upon results obtained in scientific investigation. Credit is, of course, due to the engineers who convert laboratory experiments into commercial undertakings, and to inventors for making use of scientific results in the production of instruments and devices for the convenience and comfort of man; but in both cases they are adapters of new knowledge rather than creators of it. The new field is opened by the man of science, but he is usually forgotten by those who afterwards take possession of it.

National well-being can only be secured when the close relation between it and scientific progress is understood. Discoveries which lead directly to developments of industry and manufacture may almost be left to take care of themselves, and the search for them is not likely to be neglected, but it is not the case with those for which no immediate use can be seen, yet almost all scientific research comes within that category. This is the kind of research which needs encouragement more than any other, and demands the greatest amount of originality, inspiration, and enthusiasm, to produce apparently insignificant results. The man who has zeal for work of this kind, who is a born researcher, should be cherished by his country above all others, and every advantage be offered him for the pursuit of knowledge.

When men of science ask for funds for scientific research they do not wish to bury the talents they receive or to derive personal profit from them. Whatever amount is entrusted to them is returned a hundredfold in the results achieved. How many are the researches worthy of assistance, and how small are the funds available for investigations having no obvious practical application, are understood only by men of science themselves. It would be a revelation to people endowed with a larger share of worldly riches to be present at a meeting of the committee of the British Association concerned with the allocation of grants for scientific purposes. Thirty or forty of the leading men of science in the British Isles discuss for several hours how to divide the sum of about 1000*l.* which represents the amount available from the sale of tickets at each annual meeting. There are many applications for grants from committees of each of the twelve sections of the Association, and the amount required has usually to be whittled down to 5*l.* or 10*l.*, which often does not cover the expense of stationery and postage of a research committee. Not one penny goes into the pockets of the men who are conducting the researches, yet claim after claim has to be passed, or reduced to its lowest limits, because the fund is miserably inadequate to meet the demands made upon it.

The Royal Society was unable to find the money required to print Newton's "Principia," and it was published at the expense of his friend Halley. Our scientific societies are in no better position to-day. Their members—most of whom possess but very slender means—pay by their own subscriptions for the publication of the results of their investigations. They sacrifice their leisure, and draw upon their limited resources, not only that knowledge may be increased, but also that the gain may be published to the world, which is free to make use of it.

It is difficult for the man of the world to understand the altruistic spirit which induces men of science to band themselves together in societies having for their sole aim the advancement of knowledge in particular directions; and that these men should themselves pay to enlighten and benefit others by the publication of their researches is almost incomprehensible to the selfish or money-making mind; yet such is the case. While the annual State grant made by Great Britain towards the expense of the publications of learned societies is limited to the sum of one thousand pounds to the Royal Society, several times that amount is provided each year for stationery alone used by members of the House of Commons.

The politicians who pay themselves a salary for the time they devote to party tactics and personal persiflage would be astounded if the proposal were made to provide for the support of Fellows of the Royal Society or of any other scientific institution, yet of the relative values to the nation of the work done in the two spheres of politics and

science, there can be no question. In a splendid building and surrounded with all the appurtenances of precedent and dignity, months and years are wasted in a game of finding weak points in arguments relating to subjects many of which are of doubtful national importance; while the scientific elect of the country are crowded in modest apartments to discuss discoveries which it has cost them much time and frequently much money to complete, and for the publication of which they must themselves make provision. It requires the satire of a Swift to describe the disparity of support afforded to polemics and natural philosophy by a State that owes most of its modern advance to scientific work.

There is no doubt that the greatest contributions to knowledge have been made by men who undertook their inquiries into Nature without thought of proximate or ultimate practical application or pecuniary reward. It is true also that the best kind of scientific investigation cannot be carried on in an atmosphere of commercialism, or where personal profit is the end in view. This, however, does not relieve the nation of the responsibility for seeing that the rare aptitude for original research receives the most generous encouragement. At present a scientific career is the last into which a man should enter who expects a reasonable reward for his knowledge and industry; for it is the least lucrative of all professions. The reason is that its members do not form a corporate professional body to secure for science the position which it should hold in the thought and affairs of the State; therefore, administrators and officials generally pay little attention to its claims. Scientific men should see that fuller national recognition is given to their work, and the programme in *Science Progress* will show some of the directions in which they may well effect improvements, so that the world shall recognise "the great principle that of all forms of human effort, those efforts which result directly in discovery, whether in science or in art, are by far the most important efforts for humanity."

R. A. GREGORY.

EXPLORATIONS ON THE NORTH-EAST FRONTIER OF INDIA.

AMONGST the many activities of the Indian Survey Department not the least in scientific interest is the series of exploratory surveys which have been carried out on the north-east frontier, to the north and east of Assam, in the wild and mountainous hinterland which lies between Tibet and Burma. The scientific interest of these explorations is two-fold, geographical and ethnographical. The region dealt with in the report of Colonel Sir Sidney Burrard (Surveyor-General of India) embraces the principal basins of the rivers Mekong, Salween, and Irrawaddy and the Himalayan catchment areas of the four principal feeders of the Brahmaputra, namely, the Lohit (Zayul), the Dibang, the Diháng, and the Sabansiri, and for the sheer physical difficulties offered to systematic mapping is probably unmatched by any equal area in the world.

The scantiness of population, denseness of jungle, altitude of ranges, steep precipices, torrential streams and infernal climate have so far practically barred communication between India and China and between Tibet and Burma. It is here that four survey detachments have been working intermittently from 1911 to 1914 to assist each other in cracking that old geographical nut which lay enshrined in the mountains which overhang the course of the Brahmaputra and the sources of the Irrawaddy. We have heard of the remarkable exploits of geographers, such as Captain Bailey, who traversed those regions with unexampled success and vindicated the reputation of earlier native explorers, but we have not heard much of the determined efforts of the official pioneers of scientific mapping, whose work furnishes the basis of all successful explorations.

The scientific interest of work accomplished in the field of geography is naturally great and varied, for it is comprised in a large field of 28,000 square miles of hitherto unknown and unmapped mountains. Perhaps the chief point which calls for recognition is the discovery of a gigantic snow peak (Namcha Barwa), 25,445 ft. in altitude, far to the east of Kinchinjunga. The discovery of a peak in Assam nearly as high as Nanda Devi (25,645 ft.) "marks an epoch," says Col. Burrard, "in the history of Himalayan explorations," and the further fact that the Brahmaputra cuts its passage across the Himalayas at the base of this mountain gives rise to a curious problem in mountain hydrography; for it is noteworthy that the Sutlej, the Indus, and the great river of Hunza all cut through main ranges close to the points of supreme elevation of those ranges. Is this only a coincidence, or are we to seek for a reason in the processes of construction of mountain chains?

Another interesting matter is the absence of falls in the Brahmaputra. This is a feature common to most, if not all, of the great Himalayan rivers which descend rapidly from great altitudes to the plains. There are, indeed, magnificent cascades throughout the Himalayas, and a tremendous drop is not uncommon at the point where a tributary joins its parent river, but there are no falls in the main streams.

As for the ethnographical interest of the regions under review, it is so extensive and embraces such a variety of problems that it is only possible to point out generally that here, if anywhere, are we to find the modern representatives of the very oldest of primeval Asiatic races. We are content to generalise under such terms as Tibeto-Burman, or Indo-Chinese, a vast aggregation of tribespeople who differ so widely in their social idiosyncrasies, and even in anthropological features, that there must almost certainly be amongst them survivals who can help point the way to the very beginning of the human alphabet in Asia. All information that can be obtained about them, about their physical conditions, their habitat,

their manners, methods and creeds, is of the greatest scientific value—all the greater that, as civilisation advances, opportunities for the careful study of these people will surely diminish. It is indeed the human interest in exploration which now specially calls for the attention of geographers, for such slight glimpses as we can get into the earliest stages of human existence are getting less and less. They are rapidly passing away, whilst the great wide spaces of unexplored world-surfaces where humanity is not, and never was, can well await the geographer of the future.

T. H. HOLDICH.

POTASSIUM SALTS AND AGRICULTURE.

ONE of the first results of the European War was to cut off the supply of potassium salts, which play a large part as fertilisers in modern agriculture. Our crops of potatoes and our supplies of milk are particularly dependent on abundant supplies of these particular fertilisers, and practically all the world's supply has hitherto come from the Stassfurt deposits in Germany.

The three crops that stand most in need of potassic fertilisers are potatoes, mangolds (used for dairy cows), and sugar beets. In addition, two types of soil need them for other crops: light sandy soils and peaty soils. Enormous amounts are required in Germany, where vast areas of these two types occur, and where sugar beets and potatoes are largely grown; in Sweden for the same reasons; in France and the United States for the production of sugar beets; and in this country for mangolds and potatoes. It is not surprising, then, that nearly ten million metric tons per annum are consumed.

Fortunately the conditions in British farming are such that potassic fertilisers are not indispensable, at any rate for two or three years. Potassium salts form insoluble combinations in the soil, and do not wash out; any excess not removed by the crop is therefore in safety. Further, a considerable proportion of what is absorbed by the crop finds its way back to the soil in farmyard manure, the materials sold off the farm not as a rule containing much potash. The supplies stored in the soil can be utilised to advantage by a suitable dressing of lime or chalk, which displaces the potassium from its insoluble combinations, and also by addition of sodium chloride, which has the same effect and in addition economises the consumption of potassium by the plant.

But there are sources still open to the farmer. Seaweed contains considerable quantities of potassium, which would become available on a proper reorganisation of the kelp industry on modern lines. The farm itself can also supply something. At this time of the year a good deal of hedge cleaning has to be done to make a clear way for the plough, while later on the hedges have to be cut back to keep them sufficiently low. The material is very bulky, and has to be burnt straight away; it yields an ash found at Rothamsted to contain about 10 per cent. of potash (K_2O), which is thus nearly as rich as kainit (12·5 per cent. K_2O). The hedges from each ten acres of land yield about 1 cwt. of ash, so that a 300 acre farm—quite a usual size for a holding—could provide itself with about 30 cwts. per annum if all could be collected. Unfortunately collection is a matter of some practical difficulty excepting in fine dry weather.

Taking all circumstances into consideration, however, it does not appear that British agriculture will suffer for two or three years from potash starvation, though when conditions become more normal the farmer will no doubt be glad enough to replenish the stocks in his manure shed and his soil. Up to the present it does not appear that any other of the common fertilisers will be cut off through the war. Indeed, the tendency is all the other way, and some of the supplies usually shipped to the Continent are now available for use in this country.

E. J. R.

NOTES.

THE anniversary dinner of the Royal Society, usually held on St. Andrew's Day, November 30, will not be held this year.

THE following have been elected officers of the Cambridge Philosophical Society for the ensuing session, 1914–15:—*President*: Prof. Newall. *Vice-Presidents*: Dr. Barnes, Prof. Seward, Dr. Shipley. *Treasurer*: Prof. Hobson. *Secretaries*: Mr. A. Wood, Mr. F. A. Potts, Mr. G. H. Hardy. *New Members of the Council*: Mr. J. A. Crowther, Mr. H. H. Brindley, Dr. Fenton, Mr. H. Hamshaw Thomas.

ACCORDING to the Christiania correspondent of the *Morning Post*, a monument in the form of a monolith 15 ft. high has just been completed at Christiania and is intended to commemorate the gallantry of the late Captain Scott and his companions in their Antarctic expedition. It has been subscribed for by Norwegian friends of the explorer. On the front are inscribed the names of Captain Scott and those who died with him, while at the back is a short record of the expedition.

A CASE is recorded in the daily papers of a soldier who, during a recent engagement, was shot in the forehead, the bullet passing out of the back of his head without killing or even stunning him. He remarked, "Everything seems green all round me." When in the hospital tent he still saw everything green, but otherwise made no complaint. This case appears to favour the cerebral theory of colour vision of Dr. Edridge-Green, the shock to the brain having altered the discriminatory apparatus so that impulses caused by green rays had a preponderating influence.

THE opening meeting of the one hundred and sixty-first session of the Royal Society of Arts will be held on Wednesday evening, November 18, when an address will be delivered by Sir Thomas H. Holdich, vice-president and chairman of the council. The following are among the arrangements for meetings before Christmas:—November 25, Sir William A. Tilden,

"The Supply of Chemicals to Britain and her Dependencies; December 2, Dr. W. R. Ormandy, "Britain and Germany in Relation to the Chemical Trade"; December 9, Mr. W. A. Young, "Domestic Metal Work of the Eighteenth Century"; December 16, Sir William Abney, "Testing Pigments for Permanence of Colour"; December 17, Dr. F. Mollwo Perkin, "The Indian Indigo Industry."

WE notice with satisfaction that various scientific societies are welcoming Belgian refugees who are interested to attend their meetings. The Society of Engineers has opened the offices of the society at 17 Victoria Street, Westminster, daily from 10 a.m. to 4 p.m. (Saturdays, 10 a.m. to 1 p.m.), to Belgian engineers who are now in England on account of the war, and they are invited to apply to the secretary when they are in need of any information. Belgian engineers who are unable to call are invited to send their names and addresses to the secretary so that they may be in touch with their colleagues and receive invitations to the meetings. A committee of the Linnean Society has been empowered to invite Belgian botanists (whether ladies or gentlemen) to attend the meetings of the society and to make use of the library. The council of the London Natural History Society, too, invites any Belgian refugee interested in natural history to attend the meetings of the society and offers them the use of the society's library and collections. Particulars of the meetings, which are held at Hall 20, Salisbury House, London Wall, E.C., at 7 p.m. on the first and third Tuesdays of the month, can be obtained from the honorary secretary, Mr. J. Ross, 18 Queen's Grove Road, Chingford, N.E.

MR. H. W. CODRINGTON, of the Ceylon Civil Service, has compiled a useful catalogue of the collection of the European (exclusive of Roman) and Muhammadan coins in the Columbo Museum. The Indo-Portuguese and the Dutch coinage of the period 1640–1796 are well represented in the collection, and this catalogue, which is illustrated by a good series of process plates, will be of considerable interest to numismatists.

THE Journal of the Royal Society of Antiquaries of Ireland for September is largely occupied with a guide to the antiquities of Dublin and the neighbourhood provided for the use of the meeting which was held in June last. This publication is written by the most competent authorities, is well illustrated, largely from old engravings, and contains a fuller and more judicious account of the local antiquities than can elsewhere be procured. The description of St. Doulagh's Church, with its remarkable anchorite's cell, is specially to be commended.

IN *Man*, for November, Mr. J. Reid Moir discusses the question of the striation of flint surfaces in relation to the speculations of Dr. W. Allen Sturge, who attributes the markings on flints found in north-west Suffolk to at least six minor glaciations which occurred in Neolithic times, and he thus pushes back the advent of Neolithic man to a period about two hundred thousand years ago. Mr. Reid Moir, as the result of experiments on flint scratches, points out that this substance is far from being homogeneous, and that the belief in its hardness applies only to a freshly broken, unchanged sound flint. Exposure to the atmosphere produces patination or softening. It is thus impossible that flints long exposed to the weather could retain these scratchings for a lengthened period, and those found lying on the surface may owe their striation to ordinary causes, possibly connected with agricultural operations. The composition and character of flint are so important in connection with the age attributed to implements made of this material, that a more thorough examination of flint structure and its susceptibility to striation is an inquiry which should be systematically undertaken by a committee of competent geologists and archæologists.

IN the Journal of the Royal Society of Antiquaries of Ireland for September Mrs. Brunicardi contributes an interesting summary of our existing knowledge of the shore-dwellers of ancient Ireland. The map shows the curious distribution of their kitchen-middens. They appear at only three sites on the east coast, while on the west and south they are fairly numerous, chiefly in Donegal, Galway, Clare, Kerry, and near the harbours of Cork and Waterford. The writer discusses these remains in great detail with references to the original authorities. Very little pottery and no evidence of the use of metal are found in them, and Mr. Knowles regards them as among the earliest remains we possess of the Neolithic age. These shore-dwellers appear to have been a distinct race, probably a degraded one, living almost entirely on shell-fish, periodically migrating in search of food, but possessing what may be termed headquarters to which the whole tribe sometimes returned, and this they regarded as their home.

IN *Folk-Lore* for September Mrs. B. Z. Seligmann discusses the curious customs of demon possession and devil-dancing known in Egypt as the Zâr. After a full description of the rites, she arrives at the conclusion that they may have a double origin, from Abyssinia and the Sudan. The word Zâr is clearly Abyssinian, and must have been recognised in Egypt before the opening of the Sudan by Mahomed Ali and the consequent importation of black slaves. It must be remembered that the Red Sea route has been open for more than 2000 years, while intercourse with the Upper Nile has been intermittent, generally confined to raiding and plundering. This route, again, was barred by the Christian kingdom of Aloa, which up to the fifteenth century formed a barrier between Egypt and the Sudan. But whatever date may be assigned to the introduction of the Zâr into Egypt, there can be no doubt that its present popularity among the higher classes is due to the influence of black slaves received into the harems on a footing of perfect equality. Hence their cult of the dead was soon modified into a general belief in spirits which reinforced that which had perhaps already reached Egypt from Abyssinia. Mrs. Seligmann's graphic account of these rites may be usefully compared with that

recently published by Major A. J. N. Tremearne, of Hausa customs of the same kind in his valuable work entitled "The Ban of the Bori."

WE have received from Mr. Edwards, of High-street, Marylebone, a catalogue of works relating mainly to fishes, fisheries, and angling.

Two excellent plates illustrate an article by Dr. Annandale in vol x., part 5, of Records of the Indian Museum on new and other stalked barnacles from Indian waters. Most of the species are of minute size; the most remarkable being one (*Heteralepas reticulata*) found in clusters on the spines of a sea-urchin. It is easily recognised by its "honey-pot" shape.

A MUCH compressed report, crowded with detail, by Mr. T. Southwell, on the fauna of the Ceylon pearl-banks, and a second on the food of certain marine Ceylonese fishes have been issued in the Educational Section (Science and Art) of the Ceylon Administration Reports for 1912–13. Portions, at least, of the notes are promised in another and fuller form, when it probably will be easier to grasp and assimilate their contents.

IN the October issue of *Naturen* Mr. O. J. Lie-Pettersen continues his illustrated account of the Norwegian tit-mice. The birds of Sarawak form the subject of an article in vol. ii., No. 5, of the Sarawak Museum Journal, by Mr. R. B. Williams, who has made coloured sketches of about one hundred species, from examples shot by himself. These sketches are accompanied by notes on the appearance of the freshly-killed birds and on the habits of the various species, and it is from these that the article has been compiled by Mr. J. C. Moulton.

ACCORDING to a notice in the November number of the *Museums Journal*, Dr. F. A. Lucas, director of the American Museum of Natural History, New York, disapproves, as a general rule, of large special exhibits in zoological museums, on the ground that when they are closed there is a marked falling off in the normal number of visitors. This, however, has not been the experience at the Natural History branch of the British Museum, as a result of the various special exhibitions which have been displayed at different times during the last few years; and even if it were the case, it would afford no argument for the abandonment of such temporary "side-shows."

IN addition to the gift of the type skull of the perissodactyle mammal *Pliolophus vulpiceps*, to which allusion has been made previously in our columns, Mrs. Richard Bull, widow of the late vicar of Harwich, has presented to the British Museum (Natural History) a skull and three shells of one or more of the three large species of marine turtles of the genus Lytoloma which occur in the London Clay of the Essex coast. The museum has also secured a specimen of the chelonian from the London Clay originally described by Owen as *Emys testudiniformis*, but now referred to the American fresh-water genus Chrysemys. It is in far better preservation than the type, and hitherto only known, specimen.

A GROUP of three East African buffaloes shot during the Roosevelt expedition was set up some time ago in the U.S. National Museum, amid an imitation of African scenery constructed of such material as was obtainable at Washington. This, however, was only a makeshift, and the museum has recently procured from East Africa a quantity of papyrus and reeds for the purpose of making a really vivid model of a buffalo-swamp. In the case of the papyrus the stems are slit open, the pithy interior removed and replaced by plaster, and the whole painted green. For the last few months the buffalo group has been withdrawn from public exhibition; but according to an announcement made by the Smithsonian Institution at the end of October, it was then shortly to be reinstated with its new surroundings complete.

THE October Bulletin of the American Geographical Society contains a preliminary report by Mr. R. S. Holway on the recent volcanic activity of Lassen Peak in northern California. The mountain, which rises at the southern end of the Cascade Range to a height of 10,437 ft., is an old volcanic cone from which a lava flow occurred some two centuries ago. On the north side of the bowl of the old crater, a series of steam explosions, beginning on May 30 last, has opened a new vent, from which stones have been thrown over an area more than half a mile in diameter. No freshly molten lava has been seen, and no heat has been noticeable except that of the escaping steam. Mr. Holway gives a list of twenty eruptions up to July 15. The formation of this new vent is the first recorded instance of volcanic activity witnessed in the United States, excluding the outlying regions.

WE have received from Japan the three parts of the Bulletin of the Imperial Earthquake Investigation Committee which were issued in the months of July, August, and September of the present year. The first two of these are devoted to a discussion by the able seismologist, Prof. Omori, of the eruptions and earthquakes of Asama-yama from 1911 to the date of issue. The records of the seismographs at the volcano-house of Yuno-taira and more distant localities are compared with the observations made in the crater of the volcano, the general conclusion arrived at being that the activity within this gigantic volcanic vent is now gradually subsiding. In the number issued in September, the same indefatigable observer gives a graphic account of his own studies of the Sakura-jima eruptions and earthquakes in January, 1914. The author was a member of the Commission sent by the Japanese Government to prepare a record of that eruption, which Prof. Omori thinks "may be counted, in point of the magnitude of disturbance, as one of the greatest volcanic catastrophes in modern times." An account of this outburst appeared in NATURE of January 22, 1914 (vol. xcii., p. 589). The bulletin is published in English, and the printing and illustrations reflect the greatest credit on the Japanese publishing office. More than fifty plates, including exquisite photographs with clear maps and diagrams, illustrate these three numbers, which constitute a very important contribution to the sciences of seismology and vulcanology.

THE Bulletin of the Imperial Institute (vol. xii., No. 3) contains, in addition to reports on the results of the scientific and technical work of the staff on various colonial products, a special article on the agricultural resources of the Zanzibar Protectorate by Mr. F. C. McClellan, Director of Agriculture, Zanzibar, who describes the climate and system of land tenure in this portion of the Empire, discusses questions of labour and wages, and deals fully with crops and products, the chief of which are coconuts and cloves. In the latter article Zanzibar has practically a monopoly of production. In connection with the campaign for the capture of German trade an article on the trade in palm kernels is of importance as showing that a large proportion of the exports of palm kernels from West Africa are shipped to Germany, where they are used as the source of palm kernel oil and of cake for feeding live-stock, much of the palm kernel oil being re-shipped to this country. This important trade and industry could be well carried out in this country. Other articles deal with the utilisation of waste fish as a source of manure, the tin resources of Australia, South Africa, and Nigeria, and the trade of the Seychelles. Prof. W. R. Dunstan's address at the opening of the third International Congress of Tropical Agriculture (June, 1914) is printed *in extenso*.

THE *Scientific American* for October 10 contains several features of particular current interest. In an editorial the view is put forward that in the event of conscription becoming universal, scientific men should be exempt. They are of incalculable value in the advancement of mankind, and as such their loss would entail greater sacrifices than could be compensated for by their use in the fighting field in which their efficiency and their numbers would probably be too small to have any appreciable influence. In a short note a method is given of hardening the concrete floors of factories. A mixture of 15 to 20 lb. of iron dust with 100 lb. of cement and twice that amount of sand is applied as a surface coating about an inch thick.

WE learn from the Smithsonian Institution that Mr. T. W. Smillie, who has been photographer to the United States National Museum in Washington for the last forty-five years, has gathered together and arranged for the museum a collection of ancient and modern photographic apparatus and specimens. It is claimed that this collection is the most complete in the world. It includes what is believed to be the first American camera, namely, that made in 1839 according to Daguerre's specification, for Dr. S. F. B. Moore; also a print from one of Niepce's plates made in 1824, several fine Daguerreotypes dating from 1839 and onwards, specimens of Fox Talbot's earliest process, and his calotypes, and some early examples of "moving pictures."

JUST as everyone should know something about the general rudiments of astronomy so a knowledge of the elements of our weather and climate should be universally understood in these isles. The earlier such knowledge is acquired the more natural is the interest taken in such figures and diagrams which appear in our daily papers. Besides, we all experience our "weather," and this should be sufficient to bring home to us the importance of understanding such data as are thus placed before us, and should make us wish to take an intelligent interest in some of the elementary principles. Under the title of "Weather Chart Exercises" (British Isles and West of Europe), compiled by Miss L. M. Odell, and published for the University of London Press by Messrs. Hodder and Stoughton (London), we have before us a series of exercises which have been given in connection with the explanation of the weather charts issued by the London Meteorological Office, and in the working out of climate with special reference to the British Isles. The exercises consist in drawing monthly curves of rainfall and temperature, drawing isotherms and isobars, differentiating between high- and low-pressure systems, and many other important factors regarding weather. All the data which are to be used are given in tables, printed forms and charts accompanying them so as to minimise the time spent by the pupil in unnecessary and mechanical work not really belonging to the subject. The exercises are arranged in a progressive order of difficulty and the treatment throughout is excellent and reflects great credit on the compiler. The fact that the new units (millibars), as well as the old, are employed, speaks well for the up-to-date character of the work. It may be suggested that as the map showing the "observation stations" and the "conversion tables" are so frequently to be used both of these should be printed on folding leaves at the end so as to be before the student on whatever page he or she may be working.

IN the *Biochemical Journal* (vol. viii., No. 4, p. 438) Miss M. Cunningham and Dr. C. Dorée discuss the formation of ω-hydroxyfurfuraldehyde from various carbohydrates on distillation with hydrochloric acid under the conditions generally used in estimating pentoses by the well-known Tollens-Kröber method. The formation of this aldehyde is a source of error in estimating the pentoses, but it is shown that the condensation which produces the true furfural is almost completed before the hydroxymethyl derivative begins to distil over, and by using aniline acetate test paper it is possible to distinguish between the separation of the two aldehydes, so that little error is made in the estimation of pentoses or pentosans. Light is thrown in this paper on the so-called "furaloid" constituents of plants; in all probability these are merely hexose-yielding substances, which give hydroxymethyl aldehyde on distillation with acid, the latter substance being then largely decomposed by a second distillation with acid.

IN *Science Progress* for October Dr. H. W. Bywaters gives an account, under the title "Vitamines," of recent work on nutrition, and of the light thrown by the researches of Funk, Hopkins, Osborne, and Mendel on the cause of such "deficiency diseases" as beri-beri, pellagra, scurvy, and rickets. These researches emphasise once again the importance of the part played by the "infinitely small" in vital changes, a part which has been more and more realised during recent years with the increased knowledge obtained of enzymes and similar agents. In a paper on the

biochemistry of respiration, Dr. H. M. Vernon shows how recent research points in the main to its being dependent on intracellular enzymes—in some cases purely hydrolytic, in others partly hydrolytic, partly oxidative. Dr. R. W. Hegner deals with the germ-cell cycle in animals, Mr. A. G. Thacker has a paper on extinct apes, whilst Mr. W. L. Balls considers the question of the aid to be given by science in the future to the growing and utilisation of cotton. The theories of dyeing are discussed by Mr. E. A. Fisher, the problem of smoke abatement by Mr. J. B. C. Kershaw, whilst Mr. James Huneker has a short illustrated article on tornadoes and tall buildings.

The geared turbine Atlantic liner *Transylvania* ran her trial trips a fortnight ago, and the observations of a representative of the *Engineer* who was present are of interest. There is some vibration in certain parts of the ship, but nothing to be compared with that which would be experienced with reciprocating engines. It was local, and of a very innocent description; it fact, it might be described as merely an absence of stillness. Owing to the high revolution speed of the turbines—1500 r.p.m.—the vibration speed is high. The noise in the engine-room is at present quite considerable, and is the typical roar of high-speed gearing. It is not easy to see how the noise may be eliminated entirely, in spite of the beautiful machines invented for cutting the gears. On the third-class passenger deck, gear noise disappeared totally at a distance of about 150 ft. from the engine-room entrance. On the deck above this, the noise disappeared at about 90 ft. from the companion-way. In fact, in the space used for passengers, the noise is just noticeable while listening carefully for it, and hence cannot be considered objectionable from the passengers' point of view, especially as the sound is not high-pitched.

The Carnegie Institution of Washington has issued the first part—A to H—of the "Index to United States Documents relating to Foreign Affairs, 1828–61," which is to be completed in three parts. The index is the work of Miss Adelaide R. Hasse, the head of the department of documents in the New York Public Library, and an idea of the magnitude of her task can be formed from the fact that the present instalment of the index runs to 793 large pages. In addition to the reports of Congress, the following series of documents have been indexed: the Senate Executive Journal, for diplomatic and consular appointments and treaty ratifications; the Opinions of the Attorneys-General, for decisions on questions of international controversy; the Statutes-at-Large, for acts and resolutions relating to international affairs; and the Congressional Globe and its predecessors for speeches and correspondence.

OUR ASTRONOMICAL COLUMN.

Colours of Stars in the Cluster M13 (Hercules).—When stars are too faint to be spectroscopically examined, some idea of the type of spectrum involved can be gathered from their visually observed colour. It may happen that the stars are even so faint when seen in a powerful telescope that they exhibit no colour at all; it is then that the photographic plate is called in, the sensitive film being a great differentiator of colour. In the case of star clusters the opportunity is afforded of comparing a great number of stars, and it is of extreme value to know whether the stars involved are all of one physical condition or same spectral type, or whether they show representatives of all types. Especially is this the case when it is remembered that star clusters are most remote and must therefore be of immense magnitude. The photographic determination of the colours of some of the stars in the cluster M13 in Hercules is therefore of great value in this connection, and the research which we owe to Prof. Barnard (*Astrophysical Journal*, vol. xl., No. 2, September) is one that will be read with interest. In this paper the stars are practically divided into two colour classes, namely, blue stars and yellow stars, and this has been done by comparing two photographs of the same cluster taken under two conditions. One photograph was secured with the 13-in. astrographic refractor of the Potsdam Observatory, and the other with the 40-in. refractor of the Yerkes Observatory. The optical conditions on the Potsdam photograph were such that the blue stars were relatively brighter than the yellow stars, while on the Yerkes plate the reverse was the case. A comparison of the plates thus afforded a means of separating these coloured stars, but care had to be taken to eliminate all comparisons of star images where variability might be involved. Prof. Barnard concludes that in this cluster there exist stars of extremely different types, and hence, by inference, that there are stars of all the different spectral types. The paper is accompanied by reproductions of the Yerkes and Potsdam plates and an index chart.

The Electric Arc and Spectral Line Displacements.—Numerous references have been given in this column to investigations on the causes in terrestrial spectra of displacements of lines from their normal positions. In fact, the inquiry which was started some years ago to select and adopt certain standards of wave-length of iron, etc., show that little was known about the behaviour of lines under different conditions of electric current, arc length, etc. All attempts therefore to arrive at a final selection of lines suitable as standards are of fundamental importance to spectroscopists and astro-physicists, and in this report the communication by Mr. T. Royds (Kodaikanal Observatory, Bulletin xl.) on an investigation of the displacement of unsymmetrical lines under different conditions of the electric arc will be welcomed. To find a light source giving normal wave-lengths for all classes of lines is therefore an inquiry of the first order, and the present paper is an advance in that direction. The results of the present work are summed up in a series of brief paragraphs at the end of the paper, and while only a few of these can be referred to here, the reader should consult the original bulletin. When the spectrum of the region of the arc near the negative pole is compared with that of the centre, the unsymmetrical lines are displaced in the direction of their greater widening; symmetrical lines have very small or no displacements. The displacement near the positive pole is about half that at the negative. A displacement of the same sense as that at the poles is produced at the centre of the arc by increasing the current or shortening the arc. The displacement at the negative pole is reduced if only the positive pole is supplied with the material producing the spectrum. Displacements occur in the arc *in vacuo*, but to a much smaller extent than in air, and he suggests that the arc *in vacuo* is a better source for the determinations of standards of wave-length and for comparisons with the sun's spectrum.

ANNALS OF THE ZÔ-SÈ ASTRONOMICAL OBSERVATORY.—The seventh volume of the Annals of the Zô-sè Observatory is divided into four parts, and deals with solar, double-star and cometary observations made during the year 1911, together with a discussion of some early star observations made about the year 1744. The observations of the sun are confined to spots, faculæ, and prominences, and, in addition to the observations themselves, a very complete summary is given of their distribution in both latitude and longitude, with reproductions from the drawings of the chief prominences observed. Part ii. deals with the observations, both visual and photographic, of the double and multiple stars; while the third part is devoted to the observations of comet Brooks (1911*c*) and comet Borrelly (1911*e*). In the last-mentioned part comparisons are made with the observations of others who studied these comets, and an interesting series of reproductions from photographs of comet Brooks accompany the text. The last and fourth portion is devoted to a description and reduction of a catalogue of stars observed at Pekin under the Emperor K'ien-Long in the year 1744. Two reproductions of the old Chinese charts are given, and the stars have been identified and their positions reduced to the epoch of 1875, with accompanying charts. Historically interesting are the translations of the early decrees relating to the staff of the observatory and of the preface to the catalogue.

THE DEVELOPMENT OF CHEMICAL INDUSTRIES IN THE BRITISH ISLES.

UNDER the title of "The Capture of Germany's Chemical Industries," the *Chemical News* has published (vol. cx., p. 151) an editorial article dealing with the situation opened to English chemical manufacturers by the war, a situation which has already formed the subject of an article in NATURE (September 17, No. 2342). "A unique opportunity," it is stated, "is now offered of developing industries hitherto swamped by foreign competition, and the nation relies upon the enterprise of its scientific men to attack the subject with promptitude and vigour. It is satisfactory to find that the Government has already taken the matter up, and a Committee has been appointed to consider and advise as to the best means of obtaining for the use of British industry sufficient supplies of chemical products, colours, and dyestuffs of kinds hitherto largely imported from a country with which we are at present at war."

The same subject forms the text of an important article in the *Chemical World* for October, which, after reviewing the conditions which led to Germany's occupying a practically unassailable position in this field before the war, issues a note of warning as to the methods which must be adopted if England is to gain success in the future under greatly modified conditions.

"The combination of banking facilities, system of factory management, and scientific thoroughness in detail was undoubtedly one which our manufacturers found especially formidable." If the products which Germany has made, however, are to be manufactured under English trade conditions, "not during the reign of panic but as a permanent venture, it will need a strong pull and a pull altogether by the interests which are the equivalent of those enumerated above, be they what they may. A good deal of loose talk about the effect of the patent law has been beside the mark, when it is remembered that the only protection accorded to Germany in this respect was that given to the one who got to the Patent Office first. The race was to the strong; to the one best organised. It would be idle to fight such conditions, which represent modern scientific warfare at its best, with the tools of the 1870's."

A close inspection will confirm the statement made by a director of one of the largest German aniline dye manufactories, that not 10 per cent. of their products or output was protected by patent rights but by organisation along German lines. "Equally vague has been the statement that want of free alcohol has been at the root of England's failure. With alcohol at the cost of rain-water and free trade in the patents of other countries, the result would have been much the same in the absence of that spirit of scientific and deliberate correctness and efficiency and the peculiar self-effacement of scientific workers who, directing operations in the works at practically the wages of superior workmen, have achieved such results in the worldwide endeavour on the part of Germany to outclass all other nations in this special branch of industry."

There is no doubt that in the past there has been a very great neglect by many manufacturers of the services of the properly trained chemist. The writer recalls one case of a large English chemical firm, which had been the pioneer in elaborating the processes of manufacture of a certain widely used acid; after the death of the chemist who had initiated the processes which had brought this firm a golden revenue, operations were carried on for nearly twenty years, without a single trained chemist being employed in the factory to supervise or control the processes or introduce improvements, although the processes were of a complicated character, and the output represented a value of more than 150,000*l*. per annum. By this time Continental competition had become so severe that it was almost hopeless to regain ground which had been steadily lost year by year in this particular field.

There is little doubt that the value of employing numerous chemists in chemical works is becoming more and more appreciated in this country. The supply of well-trained chemical workers which is available for the coming struggle will be the most important factor in its decision.

AUSTRALIAN WELLS.[1]

THE great Australian artesian basin is, says this report, "undoubtedly the largest artesian area in the world, but at the same time there has probably been less work done on it than on any other artesian basin known" (p. xi.). There are two conflicting explanations of the nature of this basin. According to the older official view it is artesian, using that term in its original sense for a synclinal in which water enters at a high-level intake, spreads through a permeable layer under a wide cover of impermeable beds, and is forced up through wells by water pressure from the higher parts of the water-bearing layer. The intake beds beside this Australian basin were considered to be so extensive, so porous, and so well supplied by rain and streams that there need be no fear of the supply being appreciably reduced by artificial wells.

According to one calculation the wells put down in Queensland up to 1901 used only 1/183 of the annual supply from the rain, and other estimates have calculated that the supply, without any renewal, would last for 3000 years. According to a second hypothesis, the U-tube conception of these wells is inconsistent with the variations in the head of the water and in its chemical composition, and also with its high temperatures. According to this explanation the bulk of the water is water of cisternage, supplemented to a

[1] "Report of the Interstate Conference on Artesian Water." Sydney, 1913, xv., 207. Pp. 68+40 maps and plates.

minor extent locally by rainfall; and the water is ejected, when the water-bearing layers are reached by bores, in consequence of gas pressure due to the introduction of hot plutonic water and to rock pressure due to the weight of the overlying shales on the water-bearing sands and sandstones. The question is practically important, for the policy to be followed in the administration of these well waters depends upon which explanation is adopted. The advocates of the first theory insisted that there was no evidence of any reduction on the yield of the wells and that no diminution need be feared. Some of the advocates of the alternative theory insisted that there would be a serious fall in the discharge.

The problems connected with the supply have been referred to an Inter-State Commission, which has collected much valuable evidence and an atlas of most useful maps and plates. It considered, amongst other questions, the corrosion of the tubes used for lining the wells, which in some localities rapidly decay; the irregular distribution of this corrosion illustrates the great local variations in the nature of the bore waters. Prof. Fawsitt, who gave evidence before the Commission, attributes the corrosion to the action of carbon dioxide in the presence of free oxygen.

One of the most striking maps presented to the Commission is that showing the widespread diminution from the Queensland wells; many have ceased to flow and others are greatly reduced in volume. At first the advocates of the water-pressure theory attributed such cases to the choking of the bore or to the escape of water around the bore tubes; but the Commission rejects these explanations. The distribution of the dwindling supplies in Queensland shows that the cause is very widespread, and is subject to local variations which it is difficult to explain except upon the gas-and-rock-pressure hypothesis. The Commission has adopted the water-pressure theory, but it makes two great concessions towards the later theory. Its report remarks that "the gas in these waters must undoubtedly to some extent assist in bringing the water to the surface." The Commissioners add that the rise of the water is primarily due to hydraulic pressure; but as they recognise that gas pressure assists, the old calculations as to the water levels which have been represented as the strongest argument in favour of the water-pressure theory can no longer carry much weight. The Commission has also adopted a definition of artesian water which abandons the basis of the older hypothesis.

"*Artesian and Sub-Artesian Water.*—Water struck in bores may be under ordinary atmospheric pressure, or it may be under a pressure exceeding that of the atmosphere. In the former case the water may be termed ordinary ground water; and in the latter case the water may be termed either artesian or sub-artesian. Artesian water is subject to a natural pressure sufficient to force it above the surface of the ground" (p. ix.). According to this definition all water which rises to the surface of the ground, whether through any limestone source or boiling volcanic spring, is artesian—an *extensio ad absurdum* of the term.

IONISATION.[1]

IONISATION is the process by which ions—particles charged with electricity—are produced in a solid, liquid or gas. This address is confined to the consideration of ions in gases and deals with two questions: (1) the nature of the ions, (2) the process by which they are produced. The evidence as to the nature of ions is derived from experiments on their mobility which have shown:—

α. The mobility of a positive ion depends only on the gas through which the ions are moving and not on the nature of the gas out of which the ions are formed.

β. The mobility of the ions in a gas at constant density is independent of the temperature.

γ. There is a considerable number of gases in which the mobility is very approximately inversely proportional to the square root of the density of the gas.

δ. In the case of negative ions there is an abnormal increase of mobility when the pressure is reduced below a certain value, and there is some evidence that this is also the case for positive ions at very low pressures.

Two theories of the mobilities of ions were considered, one founded on the view that the action between ions and molecules is analogous to impacts between hard elastic spheres, the other on Maxwell's theory of forces between ions and molecules varying inversely as the fifth power of the distance between them.

It is shown that (α) follows from the second theory provided the ion is a cluster of which the mass is considerably greater than that of a molecule of the gas through which it is moving. On this supposition it follows also from the first theory if we suppose in addition that all ions in a given gas are of the same size.

(β) follows at once from the second theory; to explain it on the first theory we must suppose that the size of the ion varies with the temperature in a definite way. The necessary relation can be deduced from thermodynamical principles if we suppose that the force between an ion and a molecule is analogous to that between a charged point and a sphere which is either a conductor of electricity or has a high specific inductive capacity.

(γ) requires on theory one that the ions in these gases should be of the same size, on theory two that the molecules of these gases should exert the same force on a charged point at a given distance.

(δ) follows on either theory if the ion dissociates at low pressures so that free corpuscles are present in the gas.

With regard to the process of ionisation, the first stage of this in the vast majority of cases consists in the detachment of an electron or corpuscle. Evidence as to the method by which this takes place is afforded by determinations of the velocity with which the electrons are ejected from the body.

In the case of ionisation by light or Röntgen rays, this velocity depends primarily on the wave-length of the radiation, not upon its intensity, nor, at any rate to any great extent, on the nature of the molecule from which the corpuscle is ejected. This velocity is far greater, even when every allowance is made for resonance, than can be accounted for if we suppose that the energy of the light is uniformly distributed, and that the corpuscle acquires its velocity by the action on it of the electric force in the wave. Another explanation not open to these objections was put forward.

When ionisation is due to the action of moving electrified particles, whether positive or negative, the results are quite different. The velocity of the ejected particles (δ-rays, as they are sometimes called) does not seem to vary much, if at all, with the velocity of the particles which eject them, and is of the same order whether these particles are positive rays or the much swifter kathode rays. The method of ejection by the impact of such particles was considered, and suggestions as to a possible theory and some of its consequences thrown out.

[1] Abstract of the presidential address delivered before the Physical Society on October 23 by Sir J. J. Thomson, O.M., F.R.S.

DENTAL MUTILATIONS IN NEOLITHIC HUMAN REMAINS.

MR. J. W. JACKSON, of the Manchester Museum, has reprinted from the *Journal of Anatomy and Physiology* (vol. xlix.) an interesting paper on dental mutilations in Neolithic human remains. These were first brought to light in the case of the celebrated Galley Hill skeleton, and further examples have now been discovered at the cave known as Dog Holes, on Warton Crag, Lancashire. In these latter examples the lower jaw was remarkable for the absence of the second premolar teeth on each side, and for the obliteration of all traces of the alveoli.

It is well known that during the rites of tribal initiation among the natives of Australia, the Ashantis, the Masai, and Sudanese tribes, and others, some of the lower teeth are removed. Prof. Elliot Smith has described a similar case in Ptolemaic-Roman burials in Nubia, and it prevailed in early Egypt. The occurrence of similar examples in British Neolithic interments is thus of considerable interest. Mr. Jackson is inclined to regard the practice in Britain as genetically related to similar customs elsewhere, particularly in eastern Africa, and he assumes that its occurrence among the early Egyptians some 3400 years B.C. represents a date only slightly earlier than that of the Neolithic age in Britain. It seems evident, he urges, that these early Neolithic people had retained some remnant of a rite or custom, formerly in use among themselves, or adopted from neighbouring tribes during their migration from their early home in the East.

Further, Mr. Jackson thinks we may assume from the presence of mutilations in so few of the jaws of what may be regarded as one clan or family group that, as in the case of some Australian aborigines, the significance of the operation might likewise have been lost, and that the practice became degraded into a merely optional custom through the isolation of the tribes in their northward migration, or through some advance in civilisation. In any case, the investigation may result in establishing a cultural chain linking the British Neolithic tribes with the pre-Dynastic Egyptians, by way of the Iberian Peninsula and northern Africa.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE Australian meeting of the association was remarkable for the extended nature and great interest of the excursions which had been arranged by the various local committees.

An advance party arrived in Western Australia on July 22, and were conducted by Prof. Woolnough, of the University of Western Australia, to the Irwin River, two hundred miles north of Perth, where sections were examined showing Permo-Carboniferous beds unconformably overlain by Jurassic rocks. The Permo-Carboniferous series includes near its base a bed of Conglomerate, the Lyons Conglomerate, which is shown by its numerous striated pebbles to be of glacial origin. The Lyons Conglomerate has been proved to extend for a distance of two hundred miles and is believed to be contemporaneous with similar beds in other parts of Australia and in South Africa, South America, and India.

On returning to Perth sections of pre-Cambrian slates at Armadale Brick Pits, and of crush-conglomerates of similar age at Helena River were examined, and on July 28, several additional members having joined the party, a start was made for the Stirling Ranges, 250 miles to the south, where highly contorted quartzites of unknown age were seen. Again turning northwards, the Archæan gneisses of the Toodyay railway section, which are covered unconformably by quartzite, probably of Huronian age, were visited, and, finally, an examination was made of the Coolgardie and Kalgoorlie area, both the underground workings and the surface plants receiving attention. On August 4 the party sailed from Fremantle for Adelaide.

From Adelaide a number of chemists and geologists visited Port Pirie, where the smelting works of the Broken Hill Proprietary Company were inspected, and whence a trip was made across Spencer's Gulf to the iron ore deposits at Iron Knob, whence the ore is now sent to the company's new ironworks at Newcastle, New South Wales. The party then proceeded to Broken Hill by special train, and spent a day in the examination of the underground and surface exposures of the famous lead-silver vein.

Another party visited the Cambrian glacial beds of the Sturt River and the Permo-Carboniferous tillites of Hallett's Cove, passing thence over the Upper Cambrian limestones, with Archæocyathus, of Sellick's Hill to the Inman Valley, where the striated surfaces underlying the Permo-Carboniferous tillites were first described by Stirling, and returned to Adelaide by way of the Mount Lofty Ranges.

At Melbourne, which was reached on August 13, the first meeting of the section was opened with an address by Prof. E. W. Skeats on the geology of Victoria, in which the general structure of the colony was described, particular attention being devoted to the areas covered by the official excursions. There followed a paper by Dr. T. S. Hall on Victorian graptolites, after which Prof. Johannes Walther exhibited and described a series of lantern slides in colour illustrating rock-disintegration by change of temperature and other phases of denudation characteristic of arid regions.

Prof. A. P. Coleman dealt with the climatic conditions of the Early pre-Cambrian. He referred to the desert conditions which are believed to have occurred during the Keweenawan or Torridonian period, and to the Ice age of the Huronian, and announced that recent work in Canada showed the action of water and a cool climate on the Sudbury series of pre-Laurentian age, and even in the still older Grenville and Keewatin series. "These are the earliest known formations, so that air and water worked in the usual way at the beginning of recorded geological time." Prof. Skeats read a paper on the Tertiary alkali rocks of Victoria, and Dr. H. S. Summers dealt with the origin and relationship of the same.

The morning of August 18 was devoted to a joint discussion with members of Section E on the physiography of arid lands, which was opened by Sir Thomas H. Holland, and continued by Sir Charles Lucas, Prof. W. M. Davis, Prof. J. W. Gregory, Prof. Albrecht Penck, Dr. Griffith Taylor, Mr. E. C. Andrews, Mr. A. L. Du Toit, Mr. Kenyon, Dr. W. F. Hume, Mr. H. T. Ferrar, Mr. D. M. S. Watson, and others.

The final day of the Melbourne meeting was devoted to the Tertiary deposits of south-eastern Australia. Papers on this subject were contributed by Mr. F. Chapman, Dr. T. S. Hall, Dr. G. B. Pritchard, Mr. R. Bullen Newton, Prof. J. W. Gregory, Mr. D. J. Mahony, and Mr. H. Herman, and were followed by a general discussion on the age and sequence of the strata.

The excursions during the Melbourne meeting included one to the area round Mount Macedon, where several exposures of alkali rocks, including anorthoclase trachyte, dacite, grano-diorite, and solvsbergite,

were examined, and another to the celebrated Bacchus Marsh district, where the chief points of interest were the Tertiary basaltic lava flows, the magnificent gorge of the Werribee River and the Permo-Carboniferous tillites which may be seen resting on grooved and striated surfaces of slate, sandstone, and quartzite of Ordovician age, the surfaces in some instances being as fresh as those of Pleistocene age in Britain.

Sydney was reached by rail on August 20, and here the sectional proceedings were opened by Sir Thomas H. Holland's presidential address, which will be found printed *in extenso* in NATURE of September 3, and was followed by an address on the geology of New South Wales, by Mr. E. F. Pittman. Other papers read during the Sydney session included Prof. T. W. Edgeworth David and Mr. W. S. Dunn on the Permo-Carboniferous fauna; Mr. E. C. Andrews, "The Post-Jurassic Geography of Australia"; papers on artesian water by Mr. E. F. Pittman and Mr. S. Dunstan; on metallogenetic provinces of Eastern Australia, by Mr. C. A. Sussmilch; on the genesis of the diamond in New South Wales, by Mr. L. A. Cotton; on spilitic lavas in New South Wales, by Mr. W. N. Benson; and on structural features of the coal-fields of Pennsylvania, by Prof. E. S. Moore.

The geological excursions from Sydney were (*a*) to the Blue Mountains and Jenolan Caves, and (*b*) to West Maitland and Newcastle. The Blue Mountains are capped by the sandstones of the Hawkesbury series (Trias), which rests on Permo-Carboniferous and Carboniferous rocks, which are exposed in many of the valleys, and in turn rest with marked unconformity on the Upper Devonian of Mount Lambie. The Jenolan Caves, which are excavated in limestones of Silurian age, are well known for their magnificent stalactites.

The Maitland district is chiefly of interest on account of its workable coals, and the occurrence of beds of tillite and other glacial beds in its Permo-Carboniferous series.

The section of the Permo-Carboniferous system is the most complete yet described in any part of Australia. The highest beds are those of the Newcastle series, which are of fresh-water origin, and contain some thirteen seams with a thickness of 3 ft. and upwards. These rest upon the Dempsey series, with Glossopteris and Gangamopteris, which in turn overlies the Middle or Tomago Coal Measures with several important seams.

The Upper Marine series which underlies the Tomago consists of cherts, shales, and calcareous sandstones, and rests upon the Greta Coal Measures, which contain two principal seams, the upper varying from 14 ft. to 32 ft. and the lower from 3 ft. to 11 ft. in thickness. Below the Greta Measures lies the Lower Marine series.

The glaciation appears to have taken place from a radiant point situated in a now submerged region between Tasmania and Kangaroo Island, south of Adelaide.

The members who went to Brisbane divided into several parties, some visiting the striking trachytic necks of the Glass House Mountains, while others investigated the geological structure and gold-mining industries of Gympie and Mount Morgan. The Trias-Jura coal-bearing beds of Ipswich, near Brisbane, were also visited. The beds are considerably folded and rather heavily faulted, and rest unconformably on the Gneissose rocks of Brisbane.

Excursions which had been arranged to New Zealand and Tasmania were abandoned on account of the war in Europe.

A. R. D.

EDUCATION AT THE BRITISH ASSOCIATION.

THE section met in Melbourne and Sydney. The programme had been carefully divided between the two cities, but as it was impracticable to divide the presidential address, the organising committee arranged to give special prominence to the address of Prof. Armstrong (vice-president), which was to be given in Melbourne. It was a strong plea for the further recognition of science in education and in the State, and extracts from it have already been published in NATURE (October 22, p. 213).

Following upon Prof. Armstrong's address Mr. C. A. Buckmaster read a paper on State aid to science. It was an interesting retrospect of official experience which it is scarcely possible to summarise here, though we may express the hope that the paper will shortly be published in full. Mr. W. D. Eggar discussed the position of mathematics and sciences in a liberal education. In his view the "mathematics required by university qualifying examinations is either too little or too much." From the point of view of use, it is only men in scientific professions who require more than plain arithmetic, and simultaneous quadratics is insufficient to produce æsthetic appreciation of the subject in the educated man. Instead of Euclid, which appealed to clever sixth-form boys, we have now a hotch-potch in which any proof of a theorem is accepted if it is good enough for an engineer. In science, again, everything is sacrificed to the stupid boy. Only the science which is useful is favoured. Astronomy, for example, is not usually taught at school. The problem of education after all is the opening of windows of the mind, and in the teaching of any subject we should concern ourselves with the question, How far must we go to come to a window? Cannot some agreement be arrived at as to the number and position of the windows which should be opened by a liberal education?

The second day at Melbourne was devoted to the subject of vocational education. Dr. C. W. Kimmins gave an account of the London trade schools, which are designed to bridge over the gap between fourteen and seventeen. In order to make them accessible to poor children, maintenance grants rising from 6*l.* to 15*l.* a year, and free education, are liberally provided by the County Council scholarship scheme. Definite trade instruction is also given in certain instances (tailoring and bakery), but scholarships are not awarded in these cases. The trade school has also become a necessity owing to the decay of the apprenticeship system, in comparison with which it has certain compensating advantages—it provides better supervision, it does not neglect literary subjects, it takes a completer view of the trade itself, and it provides a due balance of theory and practice. These schools have the further advantage that they are governed by a consultative committee of experts—a most important essential in their success. The cost of such schools in London works out at 15*l.* to 21*l.* a year for boys, and 15*l.* for girls. Dr. Moody described his experiences in the organisation of commercial education, and Dr. Findlay dealt with the compulsory education of youth. A new type of institution and a new type of teacher are essential. Youth needs social experience and vocational guidance as well as instruction. Little can be done until the State accepts the principle of partial control over wage-earning youth. Mr. A. D. Hall considered that all education should be vocational: only then shall we get a product fit for something, because it has been subjected to the discipline of purposeful work. He outlined a scheme of agricultural education, which

was a good deal criticised by Australian members as quite unsuited to their conditions. Mr. Frank Tate described the effort made in Victoria to redeem education from the charge of being too academic.

On the third day, the section discussed the training of teachers, in which Dr. Smyth, of the Melbourne Training College, Prof. Findlay, and Prof. Green took part. Papers were also read by Prof. Boyce Gibson on moral education; Mrs. Meredith, on domestic training in primary schools; and Miss Lilian Clarke, on the teaching of botany. All these papers aroused a good deal of interest, and excellent discussions followed.

Prof. Perry opened the Sydney meetings with his presidential address, which was published in full in NATURE of October 1. After the presidential address, the greatest local interest was roused by Prof. Netschajeff's paper on experimental pedagogics in Russia. It was chiefly devoted to a descriptive account of research work in the experimental school which he has founded in Petrograd under the auspices of the Ministry of Commerce. The work there is mainly directed to the investigation of the changes in the mental life of children as depending upon age, sex, and environment, as well as the determination of the best methods of teaching the various school subjects. The teachers' judgments upon individual children have also been the subject of psychological investigation. Work of this kind necessitates a threefold process. It begins in the laboratory itself, and passes thence to the school, coming finally to the laboratory again for discussion and further research. The body of workers attached to the school have also been engaged in simplifying and cheapening psychological apparatus. They have produced a cabinet of essentials at so reasonable a price that no fewer than 131 schools and teachers' societies in Russia have been supplied. Prof. Netschajeff presented a specimen collection of this apparatus to the education department of the University of Sydney.

Another day was devoted to the discussion of the problem of the university in its relation to State and school. Sir Harry Reichel made a strong plea for university freedom. The whole work and spirit of a university would be killed by anything like bureaucratic control. Mr. Board, Secretary for Education in the State of New South Wales, gave general support to this view. Prof. Green urged the need for greater freedom for the schools, which at present suffer from the relatively rigid requirements of university entrance. Intellectual keenness is commonly lost in the effort to meet the demands of matriculation examinations. Schools also have yet to learn that their function is not defined by the university but by the needs of the vast majority of their pupils who do not intend to enter the university at all. Dr. H. B. Gray read a paper on school training for public life, in which he pleaded for a more liberal treatment of science in the public school. Thus he would not give more than from one-quarter to one-sixth of school life to the classics. More geography, a thorough study of one modern language, and of English literature and history would then be possible, and science might get reasonable treatment. Socially, too, the public schools need reform. They suffer from narrowness of outlook, which may serve to produce rulers of inferior races but does not turn out men suited to play a great part in the newer democracies.

Prof. Mackie read a paper on the training of teachers, giving an account of the conditions in New South Wales. A discussion followed in which Prof. Findlay, Dr. Kimmins, and Prof. Green took part. All the speakers emphasised the need for greater attention being given to research and experiment in this sphere of practical work. Dr. Kimmins gave an interesting account of a London County Council scheme for an Imperial interchange of teachers—a plan which would enable Australian teachers to spend a year at home, at little cost to themselves, and with the great advantage of enabling them to learn something of their profession as practised in London.

The sectional meetings were uniformly well attended, though along with other sections it suffered considerably at the hands of the Press on account of the war. Many English visitors enjoyed the opportunity of visiting educational institutions in the various States. All were impressed by what they saw. Everywhere, and particularly in New South Wales and Victoria, we found evidence of a profound belief in education and a readiness to make sacrifices in its behalf. Over-centralisation is perhaps the greatest danger in both States—a danger which is at a minimum now owing to the personalities in actual control. We were all greatly indebted to the authorities for the descriptive literature provided, and no better statement of the general position of Australian education is to be desired than that written by Prof. Anderson in the handbook provided by the Commonwealth for the association.

RECENT ASPECTS OF MUTATION.[1]

IN recent years significant developments have taken place in connection with the study of mutations; indeed, these developments are so numerous that only a few of them can be mentioned now. The genus Œnothera has continued to be a storm-centre around which many controversies have raged, but of late a number of these questions appear to have been definitely settled. Among the recent developments may be mentioned first the authentication of *Œ. lamarckiana*, Ser., as an endemic species of the North American flora. The specimen collected by Michaux some time during his travels in eastern North America between the dates 1785 and 1796, which is now in the Muséum d'Histoire naturelle in Paris, and to which de Vries has recently directed attention, proves that this species did not originate in cultivation, as has been so frequently surmised. This shows also that it could not have come from Texas in 1860, as was stated, and it may yet be found in Kentucky or perhaps in western Virginia. This belief is founded on several considerations which I need not enter into here.

In order to show that *Œ. lamarckiana* differs in no respect from several other species as regards its history and fate, let me trace the history of certain of these species. *Œ. biennis*, L., as it now grows on the sand-dunes of Holland, where it has been naturalised since early in the eighteenth century, is identical with a form cultivated at Oxford by Morison about 1660, from Virginia. Yet this form is not now known to occur anywhere in North America, though search may yet reveal it in its native home. This *Œ. biennis* was probably the first Œnothera to be taken to Europe, in 1614. It has remained for three centuries unmodified in its new habitat, though Stomps has recently shown that it gives rise to two mutations, *cruciata* and *sulphurea*, the latter of which was already recognised as a distinct variety by Linnæus in 1737, as Bartlett has shown. Another race of *Œ. biennis*, obtained originally from the Madrid Botanical Garden, contains several aberrant forms parallel to the *lamarckiana* mutations, including one resembling *laevifolia*, and it also produces *Œ. biennis lata*.

[1] From a lecture delivered at the Marine Biological Laboratory, Woods Hole, Mass., on August 14, by Dr. R. Ruggles Gates.

The history of *Œ. parviflora*, L., is no less interesting. Morison grew it, and several early specimens are also found in the British Museum. Like *Œ. biennis*, it masqueraded under a pre-Linnæan polynomial. Unlike *biennis*, however, it does not seem to have become naturalised, in Europe, but it was preserved in botanic gardens until rediscovered by Miss N. M. Stevens in Maine in 1905, and described in full by MacDougal and Vail. *Œ. muricata* again was named by Linnæus, but had been introduced a century earlier, as shown by specimens in the Morison Herbarium.

Œ. angustissima has had a somewhat different history. I described this species from Ithaca, N.Y., last year, and afterwards found that Morison had cultivated a closely similar race of the same species. The latter probably came from Maryland, where I believe it still exists. Being a weaker species it has not only failed to become naturalised in Europe, but has long since disappeared from the botanic gardens.

It will thus be seen that the status of *Œ. lamarckiana* differs in no respect from that of other species, and experimental attempts to produce it by crossing two other species are bound to be futile. On the other hand, its open-pollinated habit allows of continual intercrossing of closely related races. But these races naturally occupied the same geographical area, and it is therefore useless to attempt, as has been done, to produce *lamarckiana* by crosses between two races or species which are geographically isolated from each other.

Another feature of *Œ. lamarckiana* which it shares with such species as *Œ. muricata* and *Œ. angustissima*, consists in the existence of several distinct races differing from each other in minor particulars. The Swedish race cultivated by Heribert-Nilsson differs from that of de Vries in a number of points, and resembles more closely the Œnotheras cultivated in English gardens. The latter also exhibit various racial differences in addition to the mutations. *Œ. lamarckiana* does not, therefore, consist of a single elementary species; and in this respect it resembles the majority of ordinary wild species. How these racial differences have originated is another question, but they are of a different order from the differences between the mutations. They exhibit one kind of diversity, the mutations another. In other words, there are here two kinds of polymorphism, and they should not be confused with each other.

The discovery that *Œ. lamarckiana* is an endemic North American species not only dispels the hypothesis that it might have originated in cultivation, but considerably weakens the Mendelian assumption that the mutants are merely hybrid combinations, and the mutation process a phenomenon of hybridisation. Since Bateson's original suggestion to this effect in 1902 nearly all the Mendelians have taken a turn at explaining the mutations in this way. We have heard of coupling of characters, duplication of gametes, and innumerable other hypotheses of this kind applied to the peculiarities of Œnothera. But it has long been obvious to critical students of Œnothera that although *Œ. lamarckiana* may be in some limited sense a hybrid, yet the mutation phenomena themselves come in a different category. And it has remained for the Mendelian assumption to be totally disproved by other lines of attack on the problem.

The analytical breeding experiments show that something other than Mendelism has to be dealt with in Œnothera, while the cytological work furnishes certain definite clues concerning the nature of the germinal changes involved. The evidence from every hand is so overwhelming that it can no longer be doubted that mutation is a phenomenon of variation, and not merely of inheritance, as Mendelians would have us believe.

It may perhaps be pointed out here that Mendelism is itself a theory merely of heredity, and a partial theory at that, dealing only with complete or discontinuous inheritance. The manner of origin of these inherited differences is a matter on which Mendelians have speculated much, and we have had complete evolutionary philosophies founded on the presence-absence hypothesis and the supposed universal "loss of factors" in the origin of *nova*. But it is obvious that a theory of inheritance, or even a knowledge of inheritance, does not necessarily throw any light on the *origin* of the differences the inheritance of which is considered. In point of fact, instances may be cited in which a character, the evolutionary development of which was very gradual, has been suddenly lost through a germinal change. It is then inherited in a discontinuous way in crosses with the "loss-mutation." The hornless condition in cattle is a case in point. To suppose that because a character is inherited in discontinuous fashion it has *necessarily* originated in a similar manner may therefore lead to wholly erroneous conclusions.

Experiment shows it to be equally untrue, conversely, that when a new feature originates suddenly it must always be inherited in Mendelian or alternative fashion. It *may* be alternative, or it may give a permanently blended result, depending in part upon the organism with which it is crossed.

An example of this kind of behaviour has occurred in breeding experiments with *Œ.* mut. *rubricalyx*. This form originated as a heterozygous mutation from *rubrinervis*, its offspring splitting into *rubricalyx* and *rubrinervis* in a simple 3 : 1 ratio, the red pigmentaton of *rubricalyx* being dominant. Extensive crosses have been made between *rubricalyx* and *Œ. grandiflora*, Solander. The latter species differs throughout from *Œ. lamarckiana* and its derivatives. The most striking differences are in foliage, buds, pubescence, and physiological reactions, *Œ. grandiflora* developing more rapidly at certain stages, and being adapted to a more southern climate.

In *grandiflora* × *rubricalyx* and its reciprocal, the F_1 hybrids are intermediate in foliage and other features, but the *rubricalyx* pigmentation is essentially dominant, though the depth of red is paler than in the *rubricalyx* parent. When the *rubricalyx* parent was heterozygous for the red (R) the F_1 contained, as anticipated, 50 per cent. with red buds (R) and 50 per cent. with green buds (*r*). In the F_2 families sharp segregation usually took place, but a few rare cases were found in which the red pigmentation had not behaved as an unmodified unit-factor, but was intermediate, *i.e.* the sepals were paler red with only traces of red on the hypanthium. By selfing such individuals it was found that a new and intermediate condition of pigmentation had been obtained, for the F_3 offspring bred true to the condition of their parent. In this way a sharp unit-character which has originated through a mutation may be permanently modified by crossing with another species.

By back-crossing the ordinary F_2 offspring again with *grandiflora* the pigmentation is also further diluted, and new conditions of stability in pigmentation are reached. Many of the details of these experiments have already been published, and here attention is merely directed to the fact that the Mendelian 3 : 1 ratio with sharp alternation between the characters appears to depend upon a condition of balance in the organism. If this condition of balance is disturbed by crossing with another species having a different metabolism then the character in question may be

modified, diluted, and blended, even though it originally appeared sharply and suddenly through a mutation in the race.

Returning to the previous line of argument, it should therefore be obvious that no theory of heredity, either Mendelism or any other, is adequate to account for the *origin* of characters, and Mendelians are responsible for much confusion of thought in failing to observe the fundamental distinction between the origin of a character and its subsequent inheritance. It is the *origin* of the character, the nature of the change involved in its appearance, and the manner and causes of its apparition, with which mutationists are primarily concerned.

It is, therefore, only after analysing many actual cases of mutation, and determining the nature and causes of the germinal changes involved in each, that generalisations can be made regarding the nature and significance of the mutation process. This has been done most completely in Œnothera among plants, and by the experiments of Morgan and his students with Drosophila among animals. Without drawing comparisons between the two series of observations and experiments, which differ in many features, reference may be made to a few of the points of view to which the work with Œnothera has led.

In the first place, as already pointed out, it has become clear and indisputable that mutation is a phenomenon of variability and not merely of inheritance. The breeding experiments and the cytological investigations have co-operated in proving this thesis, and thus eliminating the swarm of Mendelian hypotheses. In the second place, we now know that mutation, at least in Œnothera, is a composite process. Each mutation is in a new direction, and represents a different kind of germinal change. It is quite erroneous to suppose, as Heribert-Nilsson has done, that the various mutations of Œnothera fall into plus and minus series. Any such classification is of the most superficial kind, and the cytological investigation of the various mutants has done more than anything else to throw light upon the real nature of the change involved in each case.

It may be worth while to observe here that the multifarious nature of mutations, representing as they do departures in many directions from the parent stock, is in harmony with present conceptions of certain general features of animal phylogeny, according to which many lines of divergence appear to have departed simultaneously from a common stock. On the other hand, orthogenetic phylogenies, of which there appear to be many examples in the palæontological record, must depend upon other principles which are not here considered.

When we analyse cytologically the different mutants of Œnothera they are seen to fall into at least four or five categories. We may mention :—

1. Duplication of a single chromosome to give 15.
2. Hypothetically, in a case soon to be published, a second duplication, to give 16 chromosomes.
3. Triplication of the whole gametophyte series of chromosomes, giving 21.
4. Duplication of the whole sporophyte series, giving 28 chromosomes.
5. The large class of mutations in which no change in chromosome number occurs.

The latter will be referred to again later. They really include many diverse types of change, and only agree in not having a visible structural change in the nucleus.

The peculiarities of the mutants *lata* and *semilata* are constantly associated with the presence of fifteen chromosomes instead of fourteen. In 1908 the meiotic irregularity which leads to the formation of a germ cell, and later an individual, having an extra chromosome was first observed. The same unequal chromosome distribution has since been observed in several derivatives of *Œ. lamarckiana*, and also in wild *Œ. biennis* from Woods Hole, showing that these are all capable of producing *lata* mutations. It seems obvious that the mutation occurs when a chromosome passes into the wrong germ cell in meiosis, and that the peculiarities in foliage and habit exhibited by *lata* and *semilata* result from the fact that all the nuclei of the plant contain a complex of fifteen instead of fourteen chromosomes. The extra chromosome is, evidently from its origin, a triplicate of a pair already present in other forms, and apparently any member of the seven pairs may become the extra chromosome. The obvious resemblances and differences between this and the accessory or sex chromosomes need not be considered here.

The phenomenon of tetraploidy, now known to be exhibited by many species of plants and animals, first derived evolutionary significance from the fact that *Œ.* mut. *gigas*, which de Vries found to originate suddenly from *Œ. lamarckiana*, is tetraploid, having twenty-eight chromosomes. The tetraploid species of Hieracium, Antennaria, Drosera, Viola, Gyrostachys, Potentilla, and many other genera have obviously originated in a similar manner, and in the phylogeny of some families this doubling has occurred two or three times successively, so that the process is one of much evolutionary interest. The precise manner in which the doubling of the chromosome series occurs is not yet entirely clear, but it is obviously a different process from the duplication of one chromosome which gives rise to *lata*.

In the majority of mutations there is no obvious morphological change in the cell, and it appears that in such cases the ultimate change is chemical. These mutations fall into several categories differing in their hereditary behaviour. Although this matter is too involved to consider in detail here, reference may be made to what appears to be the probable basis of mutations which exhibit simple Mendelian behaviour when crossed with their parent race. We may take as an example the case of *Œ.* mut. *rubricalyx*, which originated from *rubrinervis* in cultures in 1907, and has never occurred before or since so far as known. The original mutant was heterozygous, its offspring yielding *rubricalyx* and *rubrinervis* in the ratio of 3 : 1. A homozygous race has since been obtained.

The origin of such a mutant can be adequately explained on the assumption that the substance of a single chromosome underwent a chemical change of such character that the activities of the chromosome in the whole complex of the cell led to the production of quantities of anthocyanin where it had not been produced before or where it had been produced only in small amounts. Of course, this change may be confined to one portion of a chromosome, and does not necessarily affect the whole body of the chromosome. The behaviour of mutations which exhibit a simple dominant or recessive unit-difference is fully accounted for by this hypothesis. It may be said that this merely assigns the phenomenon to the chromosomes without further analysing it. But such hypothetical changes in chromosomes are strictly analogous to the mutations which many bacteria are now known to undergo, and if such simple organisms as bacteria can experience sudden changes in structure and function it is in no way improbable that chromosomes can do likewise.

We may even explain in this way the origin of "duplicate genes," such as have been described by Nilsson-Ehle in wheat. In some families he obtained a ratio of approximately 15 : 1 for red, and absence of red in the glumes; in other families the ratio 3 : 1 was obtained. It appears that in the former case two

independent "determiners for red" are present in the germ cells. This condition receives a reasonable explanation if we assume that two chromosomes, belonging to different pairs, have each undergone the change which leads to the production of red in the glumes.

It would take us too far to attempt to analyse the various other types of mutations which are now known to occur, but we may refer to one other case. The origin of *Œ.* mut. *nanella* cannot be explained in the same way as that of *Œ.* mut. *rubricalyx*, for its hereditary behaviour is different. Not only is *nanella* recessive in comparison with *rubricalyx*, which is dominant, but when we cross *lamarckiana* with *nanella* we obtain both parent forms in F_1, and both afterwards breed true. If the behaviour were Mendelian, the dwarfs should appear first in the F_2. On the other hand, *rubrinervis* × *nanella* produces *lamarckiana* and *rubrinervis* only in the F_1, and *nanella* in the F_2. The only explanation of this behaviour that has been offered is de Vries's hypothesis of labile pangens. However we picture the change from *lamarckiana* to *nanella*, it has happened differently from the mutations previously mentioned, and de Vries's supposition that splitting in such cases occurs in F_1 or F_2 according to whether the character is present in the labile or stable condition is the only hypothesis that meets the case.

From the instances already mentioned it will be seen that mutation is a multifarious process, and the greatest need of the present time is the analysis of many individual cases through combined cytological and experimental study. Such analyses will lead to a better understanding of the nature of germinal changes and the way in which they contribute to evolutionary progress. The study of inheritance, Mendelian or otherwise, is useful and entertaining, but behind it lies the question as to how and why Mendelian and other differences arise. We have seen that a bewildering variety of germinal changes occurs, and their study opens a vast field of investigation which has scarcely as yet been touched upon. When we know more of the nature of germinal changes and the laws and causes of their occurrence it should be possible to apply the knowledge more directly to problems of phylogeny.

To me, the most significant distinction between mutations and fluctuations, or germinal changes and continuous variations, lies in the fact that the former are inherited as wholes, though it may be only in a fraction of the offspring; while the latter are partially inherited and are also more amenable to the environment. Darwin relied chiefly upon what we call continuous variations, because the complete inheritance of "single variations" or mutations was then unknown. It does not follow, however, that the latter furnish the whole of the material for evolution, and I am inclined to believe in a large borderland between these two categories of variations, which is at present unexplored.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE London County Council has arranged for a series of five lectures entitled "The Natural History of Some Common Animals," to be given at the Horniman Museum, Forest Hill, on Wednesday evenings, at 8 p.m., commencing yesterday. The lectures will be illustrated by lantern slides and specimens; each will be complete in itself, and there will be no charge for admission.

WE have received from the University of Sydney a copy of an interesting publication entitled "Bibliographical Record of the University of Sydney, 1851–1913." It is chiefly composed of lists of the publications of the members of the University staff, and of its research scholars. The titles of original papers in the various subjects of university study, and of treatises and text-books published from time to time, run to eighty-four closely printed pages, and form excellent testimony to the ability and industry of the members of the University and to the value of their contributions to our knowledge.

WE are informed that the 1914–15 session of Hongkong University commenced on September 14 with a good entry of students; eight entered from the province of Chihli and several from the Straits, Shanghai, etc. Since the last session the staff has also increased, the latest addition being Mr. W. Brown, a lecturer in mechanical engineering. There are now seventy-six students in the university studying engineering, and the British staff in the engineering faculty consists of the Taikoo professor, five lecturers and an electrician. Numerous visitors are attracted by the magnificent equipment presented by British manufacturers.

A SUPPLEMENT to the original "Catalogue of Books on the Useful Arts" in the central libraries of Newcastle-upon-Tyne, which was published in 1903, has been prepared by Mr. Basil Anderton, the public librarian, and issued by the Public Libraries Committee. The present catalogue covers the accessions to the library during the years 1903–14 and includes the titles of volumes in the lending libraries as well as those in the central reference library. Dewey's decimal classification is adopted, and the index will guide readers straight to the group of books they desire. Mr. Anderton and his staff may be congratulated not only upon the excellence and completeness of their catalogues, but also upon the comprehensive collection of technical literature which they have been enabled to provide for the use of students in their area.

THE issue of *Science* for October 23 contains the following announcements of bequests and gifts in aid of higher education in the United States. Phillips Academy, Andover, Mass., receives a bequest of about 92,400*l.* under the will of the late Mr. Melville C. Day, of New York, who died in Florence, Italy. This amount is the residue of the estate. At the termination of a life estate created for the benefit of a friend, Phillips Academy will receive a further sum of about 9000*l.* The late Mr. F. W. Dohrmann, for a number of years a regent of the University of California, has bequeathed 1000*l.* as a loan fund, for loans to members of the faculty to tide them over times of illness or other emergency. Miss Ellen B. Scripps has made a gift of 7000*l.* (in addition to 12,000*l.* previously subscribed by herself) for a pier, pumping plant, and additional equipment for the Scripps Institution for Biological Research, at La Jolla, near San Diego, California. For its maintenance she gives 2000*l.* yearly to the University of California.

A CERTAIN number of Belgian professors are now assembled at Cambridge, as well as an increasing number of students from Louvain, Liège, Ghent, and Brussels. In view of the appeal issued by the Belgian Government for volunteers, it has been decided in consultation with the Belgian Government, that only such students as are physically unfit for military service, or have been rejected for other reasons by the Belgian authorities, and are in possession of a certificate to that effect, can be accepted by the Cambridge hospitality and academic committees. It has proved impossible for Louvain University to transfer its corporate and official existence to Cambridge, and conse-

quently no attempt is to be made to organise official courses of study, to institute examinations, or to grant diplomas. But an endeavour is being made to combine systematic instruction on the lines of the Belgian universities with the requirements of refugee students and the possibilities of an incomplete Belgian teaching staff. The faculties of philosophy and letters, law, and engineering are so far most favourably placed. All students making application are asked to give their name, faculty, and university, and to state whether they require hospitality or can contribute to their maintenance. All applications should be sent to Mr. J. T. Sheppard, King's College, honorary secretary of the general committee, or to Mr. E. Bullough, Gonville and Caius College, honorary secretary of the academic committee.

The November issue of the *British Review* includes an article by Mr. J. G. Vance, on the University of Louvain. The University was founded in 1425, but as it was before the arrival of the invading Germans in Louvain, it had known only eighty years of life. Mr. Vance traces its varying fortunes from its foundation until the beginning of the nineteenth century; but the most interesting and illuminating part of his essay is his sympathetic account of the part the University has taken in the national life of Belgium in recent times. In 1834 the undergraduates numbered only eighty-six; after twenty-four years of vigorous life, there were fewer than 800; in 1855, about 1700; in 1909, about 2300; while within the last year the total has run up to 3000. Yet Belgium, with a total population of some seven millions, has four universities. No subsidy or grant of any kind has ever been received by the University from the State, the province, or the commune. The University is maintained entirely by the devotion and sacrifice of Belgian Catholics. "Rich and poor have contributed now for some eighty years to build up the University, which has been a common charge and a common burden. Every priest holding any position in any of the six Belgian dioceses pays an annual university tax, varying according to his rank and means, from five to a hundred francs. In every Catholic chapel and parish church there are two collections every year on behalf of the university, which is known to every Catholic, whether he be farm-labourer or barrister, as 'alma mater.' Lastly, a house-to-house visitation is made once a year by the curé of all the parishes, with a view of collecting and encouraging subscriptions for the same purpose."

A copy of the calendar for the current session of the University of Sheffield has been received. It gives full particulars of courses of instruction provided in the various faculties in preparation for the degrees and diplomas of the University. In common with our other modern universities, the University of Sheffield has a flourishing faculty of applied science in which degrees of bachelor, master, and doctor of engineering and metallurgy are conferred under the conditions specified in the calendar. A bachelor of engineering degree in mining has also been instituted. For students who for various reasons do not find it convenient to graduate, courses for associateships in the faculty of applied science have been arranged. Among numerous other arrangements made to meet the needs of the community served by the University may be mentioned a two years' course of work in the University and the Sheffield Training College of Domestic Science. The scientific portion of the work is taken at the University, and the technical studies in cookery, laundry, and housewifery at the training college. The calendar also gives details of a comprehensive scheme of University extension work designed to provide the means of higher education for persons who are engaged in the regular occupations of daily life. The University is also able to offer for competition a generous supply of scholarships, fellowships, exhibitions, and prizes. The arrangements in the more ordinary faculties comprised in University work are very complete and compare favourably with those of other institutions of higher learning.

SOCIETIES AND ACADEMIES.

London.

Royal Society, November 5.—Sir William Crookes, president, in the chair.—Sir William **Crookes**: Acquired radio-activity. Various objects, diamond, ruby, garnet, quartz, gold, platinum, etc., also the phosphorescent substances yttria, calcium sulphide, zinc blende, and barium platinocyanide, are bombarded in a high vacuum by kathode rays, and in no case can any permanent activity be recognised either by photographic or electrical means. Exposure to radium emanation confers temporary radio-activity on all bodies that have been tried, apparently due to the condensation of the emanation on the surface. This transient activity can be completely removed by washing in dilute acids. Many substances become coloured by direct exposure to radium, the colour depending on the substance. Diamond takes a full sage-green tint, the depth of tint depending on the time of exposure to the radium. In addition to change of colour, diamond also becomes persistently radio-active, continuously giving off α, β, and γ rays. The acquired colour and activity withstand the action of powerful chemical agents, and continue for years with apparently undiminished activity. Removing the surface by mechanical means removes both colour and radio-activity. The appearance of an auto-radiograph made by placing an active diamond crystal on a sensitive photographic plate, and the visual examination of its "scintillation" luminosity, suggest that there is a special discharge of energy from the corners and points of the crystal.—Hon. R. J. **Strutt**: Luminous vapours distilled from the arc, with applications to the study of spectrum series and their origin. II. (1) The conducting properties of a luminous jet of mercury vapour distilled from the arc *in vacuo* have been examined. The current depends on the shape and position of the kathode introduced into the jet, and is independent of the position of the anode. In the case where the anode is reached first by the stream of vapour, and a net electrode is used as kathode, all the positive ions may be taken out of the vapour that passes through the kathode. (2) The luminosity of the jet is unaffected by the removal of negative ions at the anode, but is quenched by removal of positive ions at the kathode. Although the removal of negative ions in the latter case is not complete, it is considerable enough to show conclusively that the luminosity is independent of the number of negative ions present. Thus the luminosity is not due to recombination of ions. (3) Experimenting with other metals as well as mercury, it is found that the various lines of a spectrum are not, in all cases, equally extinguished when the jet of luminous vapour passes through a negatively electrified net. Thus the lines of the subordinate series of the sodium spectrum apparently all lose intensity in the same ratio; but the D line of the principal series is much less affected. (4) The jets formed by arsenic and antimony, which show band spectra consisting of large numbers of uniformly spaced bands, are not quenched by passing through a negatively electrified net. The luminous centres appear therefore to be uncharged in these cases.—Prof. J. N. **Collie**, H. S. **Patterson**, and I. **Masson**: The production of neon and helium by the electrical dis-

charge.—Prof. C. H. **Lees**: The flow of viscous fluids through smooth circular pipes.—F. O. **Rice**: Quantitative measurements of the absorption of light. I.—The molecular extinctions of the saturated aliphatic ketones. The absorptive power of fourteen of the saturated aliphatic ketones has been measured quantitatively with an ultra-violet spectro-photometer. It was found that previous observations by other authors were inaccurate owing to the presence of impurities in the ketones. The general results of the present observations are considered from two points of view, namely, the position of the absorption band and the maximum absorptive power. The wave-length of the absorption band depends upon the number and position of the alkyl groups in the side-chain, and tends to increase with the number of CH_3 or CH_2 groups.—Prof. W. M. **Thornton**: The ignition of gases by condenser discharge sparks.—E. G. **Bilham**: The spark spectrum of nickel under moderate pressures.

CAMBRIDGE.

Philosophical Society, October 26.—Dr. Shipley, president, in the chair.—H. H. **Paine** and G. T. R. **Evans**: The conductivity of extremely dilute acid and alkali solutions.—N. **Wiener**: Studies in synthetic logic.

PARIS.

Academy of Sciences, October 27.—M. P. Appell in the chair.—Gaston **Darboux**: Partial differential equations of the second order with two independent variables and the relations of Laplace formed with such equations.—André **Blondel**: The theory of alternators.—M. **Coggia**: Observation of Lunt's comet 1914*b* made at the Marseilles Observatory. Position given for October 21.—M. **Bigourdan** communicated a telegram received from Comas Solà, director of the Fabra Observatory at Barcelona, giving the positions of a comet, possibly Encke's comet.—B. **Berloty**: Observation of the solar eclipse of August 21, 1914, at Ksara.

NEW SOUTH WALES.

Linnean Society, July 29.—Mr. C. Hedley, vice-president, in the chair.—E. F. **Hallmann**: A revision of the Monaxonid species described as new in Lendenfeld's "Catalogue of the Sponges in the Australian Museum." Part ii. The second part of the revision deals with the species (twenty-four in number) assigned by Lendenfeld to the families Homorrhaphidæ and Heterorrhaphidæ. Of these, five have not been identified; the remainder have been redescribed and figured. With few exceptions, the original descriptions have been found to be inaccurate and misleading, a number of them even confusing the external features of one species and the internal features of another; and, in the case of two of the species, the figures given are those of sponges not described in the catalogue at all.—J. H. **Maiden**: Further notes on the botany of Lord Howe Island. Part v. A description of a species of Plantago deemed to be new is offered. The paper contains notes on the vegetation of the summit of Mt. Gower by Mr. Hedley, who, and also Mr. W. S. Dun, placed his collections at the disposal of the author. Notes on the vegetation of the Admiralty Islets are given, together with critical observations on some introduced and other plants, the occurrence of which on the island was hitherto considered to be uncertain. Some notes on synonymy are included.—E. **Breakwell**: A study of the leaf-anatomy of some native species of the genus Andropogon (N.O. Gramineæ). Plants representative of seven species have been examined. In respect of anatomical structure, these fall into three groups.

August 26.—Mr. W. S. Dun, president, in the chair.—E. F. **Hallmann**: A revision of the Monaxonid species described as new in Lendenfeld's "Catalogue of the Sponges in the Australian Museum." Part iii. The concluding part of the revision deals with the families Desmacidonidæ and Axinellidæ. Several of the species described are new—among these being *Histoderma actinioides* and *Raspailia agminata*, examples of which are figured in the catalogue erroneously, in illustration of *Stylotella polymastia* and *Halichondria rubra* respectively.—F. H. **Taylor**: The Culicidæ of Australia. Part i. Seven species, referable to six six genera—Stegomyia (1), Ædimorphus (1), Culicada (2), Culex (1), Skusea (1), and Menolepis? (1)—are proposed as new, together with one variety. Additional records, for a number of previously known species, are included.—W. N. **Benson**: Petrological notes on various New South Wales rocks. The paper describes briefly collections made in various parts of New South Wales. Nullum Mountain, near Murwillumbah, consists of granophyre intrusive into Palæozoic schists. It is associated with dykes of trachyandesite, and a rock composed almost entirely of andesine. A well-known basalt-dyke at Gerringong contains abundant inclusions of alkali-felspar gneiss, granodiorite-gneiss, quartz-schist, and a few inclusions of gabbro. Interesting reactions occur between the xenoliths and basalt. Granitic inclusions are recorded from the volcanic necks of Dundas and Norton's Basin. The peculiar, green, fibrous decomposition-product of olivine, that occurs in the basic xenoliths of Dundas, and in the majority of the olivine-basalts of the Sydney district, is recognised as bowlingite.

VITALISTIC BIOLOGY.

(1) *The History and Theory of Vitalism.* By Prof. H. Driesch. Authorised translation by C. K. Ogden. Pp. viii+239. (London: Macmillan and Co., Ltd., 1914.) Price 5*s*. net.

(2) *The Philosophy of Biology.* By Dr. J. Johnstone. Pp. xv+391. (Cambridge University Press, 1914.) Price 9*s*. net.

(1) IT is a somewhat melancholy reflection for those who had the pleasure of listening to Prof. Driesch's brilliant lectures on "Vitalism" at King's College last year, that owing to the outbreak of the present war Prof. Driesch may be at this moment engaged in armed conflict with some of his then hearers. Few German men of science had more friends in England than Prof. Driesch, and few had a warmer appreciation of England. One of his very earliest pieces of work was accomplished in the marine station at Plymouth.

In the volume before us Prof. Driesch is dealing not with facts but with the history of the idea of vitalism, the idea, that is to say, that there is at work in organic beings some agency not to be discovered in inorganic things, and that the peculiarities of living matter are not to be explained by its physical and chemical structure, but by an organising "something" within, which continually modifies this structure in order to achieve an "end." Beginning with Aristotle, Driesch recounts for us the views of a series of vitalistic naturalists and philosophers ending and culminating in himself. It would indeed be a perilous undertaking were we to attempt to criticise in detail the account which he gives of the earlier vitalists, among whom are included, not only Aristotle and many of the older naturalists, but Kant, Lotze, and Schopenhauer, and it would have but little interest for the readers of NATURE. The scientific man, as distinguished from the metaphysician, takes only a minor interest in the views of early naturalists, who dealt with imperfectly known and ill-understood data, and still less in those of dealers in abstractions like Kant. Prof. Driesch, with a daring which we can only humbly admire, endeavours to make clear what Kant really meant. Perhaps we may remind him that another German philosopher, Paulsen, has defied anyone to find a rational meaning in a good deal of what Kant wrote, adding that it is only to be explained psychologically as due to the pull of tendencies which dragged Kant's mind now in one direction, now in another.

The book concludes, as we have intimated, with an account of Driesch's own views, but as these are pretty faithfully reproduced in the second volume which we notice in this review, we may defer criticism of them. We should like, however, to protest in the strongest manner against the scornful way in which Driesch refers to Darwin. "Darwin—left the question of variability open, a course which reduced his doctrine to the self-evident proposition that what was not capable of existence could not exist." "Darwinism—explained how, by throwing stones, one could build houses of typical style."

When we contrast the work of Darwin, based on a life-time of study and on the broadest possible survey of the fields of zoology and botany, with that of his critic, which may be described as an inverted pyramid based on myopic concentration on a few facts of development, and contrast, further, the influence which the theories of the two men have had on contemporary thought, we are forced to the conclusion that to Prof. Driesch, as to many of his countrymen, the Lord hath denied a sense of humour.

Darwin, taking for granted the known peculiarities of living beings seen every day around us, and pointing out the result of the impact of the known forces of the environment on these peculiarities, sought to prove that a world something like the present one must result from purely natural causes; he is neither mechanist nor vitalist. Driesch at the close of his book tells that he supposes phylogeny to be a "supra-personal evolution." Which view, we may ask, is more helpful as a working hypothesis?

(2) Mr. Johnstone's book may be perhaps described as a combination of Driesch and Bergson. Its object is to support vitalism, and to combat the mechanistic view of life. Mr. Johnstone, who is a biologist distinguished for his researches into problems of marine biology, has the merit of putting his case in clear, well-written language, and although he has to deal with philosophical problems he avoids philosophical technical terms as much as possible, so that the ordinary reader has little difficulty in following him. On the principle, apparently, that any stick is good enough to beat a dog with, Mr. Johnstone employs arguments of totally different, and somewhat incompatible, kinds to enforce his position. He begins with a chapter entitled "The Conceptual World," which is a statement of the idealistic position, and really assists him not at all. For this position merely affirms the fact, obvious on reflection, that experience as *I* receive it implies at least an *I* who perceives it, and who is as real as the experience. The logical outcome of this, as Driesch has phrased it, is, "The world is

my phenomenon," so that there must be at least one observer distinguished from what is observed. But in life and practice we all know, though we cannot prove, that there is a similar "*I*" behind many of the objects which we perceive, viz., our fellow men and women. How far there is anything similar to human personality behind the other animals and behind plants he would be a bold man who would say. So far, indeed, as this argument is valid, it is valid against physical science as much as against "mechanistic biology." The idealistic argument is followed by a long chapter, the object of which is to persuade us that there is something very mysterious and unchemical about the synthesis of carbohydrate by chlorophyll in the presence of sunlight.

We then reach the root of the matter, which is the impossibility of explaining on chemical and physical principles the growth of the organism through the embryonic stage from the egg. This, indeed, is the citadel of Driesch's position. We have to try to account for the fact that a portion of an egg or of a blastula of an Echinoderm is capable of giving rise to a whole organism, and Driesch has no difficulty in showing that there is no conceivable machine-like arrangement of parts which will account for this. But, indeed, one has only to read Weismann's hopeless attempts to explain the regeneration of limbs on his "determinant" theory to be convinced of this. The best answer to Driesch is this: "Suppose we admit that we cannot explain these phenomena by physics, what alternative explanation have you to offer?" Of course, we are all familiar with the answer: "Living beings are inhabited by 'entelechia,' which guide their activities towards predetermined ends." But such an answer does not assist us. To put forward an unknown entity as the cause of phenomena which we cannot unravel is not to explain, but in reality to give up the attempt at explanation.

"Materialism," as known to practical biologists, is really only the modest and praiseworthy attempt to penetrate a little into the working of living things by *comparing* the processes which go on in them with chemical processes in inorganic nature. But if everything is due to an entelechy, very many insoluble questions arise. Allied species are believed to be genetically related to one another; how are their different entelechies related? Is there a possibility of entelechies being modified? Or, again, if by inverting a frog's egg in the two-cell stage we can cause it to produce a double-headed monster, how is it that the entelechy is so easily baulked of its purpose? If, however, we assume that there are in eggs *organ-forming substances*—and in some cases we can prove this by direct observation, we may have to admit that these substances are very remarkable and unparalleled in inorganic objects, but at any rate we have hold of a concept with which we can work. For a substance can be divided into two, and it may be evenly distributed throughout an egg as in Echinodermata or localised as in Annelida and Mollusca, and thus we are enabled to understand why a portion of an Echinoderm egg will produce a whole organism, but why a part of a Molluscan egg will only produce a part of an organism.

Other instances of similar hypotheses could be mentioned which assist in binding together the facts observed in the behaviour of living things and in elucidating the laws which govern them. The use of such hypotheses may be regarded as neither vitalistic nor mechanistic, but as plain common-sense applications of the inductive method. In this way, and in this way alone, it seems to us, shall we ever make progress with "explanations" of the phenomena of life, for all "explanation" in the last resort consists merely in putting together similar things. When, however, we have finished with the explanations of Driesch, both as related by himself and as given by his admirer, Mr. Johnstone, we are left in a mental fog—no great guiding principles to bind together vital phenomena emerge, and the conviction grows that whatever be the right method of tackling the phenomena of life it is not that of Driesch.

E. W. M.

BRITANNIC GEOGRAPHY.

(1) *The British Empire beyond the Seas: An Introduction to World Geography.* By Dr. Marion I. Newbigin. Pp. xii+351. (London: G. Bell and Sons, Ltd., 1914.) Price 3*s*. 6*d*.

(2) *The British Isles.* By Dr. F. Mort. Pp. xi+231. (Cambridge University Press, 1914.) Price 3*s*.

(3) *Argyllshire and Buteshire.* By P. Macnair. Pp. x+161. (Cambridge University Press, 1914.) Price 1*s*. 6*d*. net.

(4) *Geological Excursions round London.* By G. MacDonald Davies. Pp. vi+156. London: T. Murby and Co., n.d.). Price 3*s*. 6*d*. net.

(1) MISS NEWBIGIN'S work is always lucid, and she brings the facts of geography into a happy correlation. The continental shelf of North America is thus connected (p. 110) with the accumulation of the Newfoundland Banks, and through them with the codfisheries. The size of Australian sheep-farms (p. 147) is explained by the peculiarities of the

rainfall. The climate of Cyprus is first discussed (p. 35) on account of its contrast with that of Mongonui in New Zealand. The world-wide view of phenomena is never absent, and a pupil who reads these pages will cease to regard the British Empire as so many isolated red patches on a map.

The various divisions of the Empire are arranged according to their climatic conditions. British Columbia is thus treated, as having a "maritime temperate climate," apart from Canada east of the Rockies, which "may be more justly compared with eastern Europe and temperate Asia." Agriculture and forestry are properly regarded as the fundamental industries that depend on climate, and many interesting statements are made as to the modes in which labour-difficulties have been met. The questions and exercises encourage further reading; we are, for instance, asked to consider the right food for our coolies, and what we should sell, as Egyptian peasants, in order to pay our taxes. We have noticed only one tiny slip; the question on p. 333, "Why do you think the islanders rejoice so greatly when this worm appears?" does not quite express the meaning of the author.

(2) Dr. Mort describes the British Isles in the modern manner that now appeals to secondary schools, and his references to the geological structure of the country are sufficient to lead the pupil to ask for more. In later work a school may well use the volume on the geography of its own county provided by the same educational press, and it will be found that Dr. Mort has laid a good foundation for more detailed local study. References to castles and the holding of gaps make us inclined to think that more might be made of the influence of structural features upon British history. No young mind that can appreciate the rise of the industries of Sheffield or of ship-building on the Clyde should remain unmoved at Portnaspania or the Roman Wall. The references to the Devon seamen (p. 133) are admirable. The illustrations are well selected to show varied types of scenery. The scarped plateau of Ben Bulben (Fig. 79) is due to limestone, and not, as is stated, to Millstone Grit.

(3) Mr. Macnair's acquaintance with the geology as well as the antiquities of his country makes him an excellent guide to the mountainous lands of Argyll and Bute. This volume of the Cambridge Geographies is issued with rounded corners, and is thus all the better as a companion for the numerous travellers who start from Glasgow for the sea-lochs and the isles. General considerations are introduced in the earlier pages, and we notice that the author, while laying stress on glacial erosion, points out that the fiords have been developed "along the geological grain of the country," and sometimes across this grain. He does not, however, refer to the probability of the weakening of the land by cross-fractures before the ice-action set in. We are glad to see an Oligocene rather than an Eocene age assigned (p. 22) to the Cainozoic lavas. The account of the geology of Arran is also well brought up to date. In the index to the geological map, however, the word "chalk" should be "Cretaceous"; and should not "ferriferous," on p. 59, be "ferrous"?

The diminution of the highland population through the attraction of other fields is strikingly seen in the fact that Argyll, on the edge of the prosperous Central Valley, has lost 30 per cent. of its population since 1831. The county was long a battle-ground, owing to its position between the lowland and the western isles, and the author well remarks that perhaps the greatest date in its history was the arrival of Columba at Iona in 563.

(4) London remains the home of sincere amateurs in natural history, and the quiet woods and byways on the edges of its basin in these days tempt the walker more and more. Mr. Davies guides us from convenient railway-stations to view-points or famous sections where we may appreciate the structure of the hills. A good coloured geological map is given as a frontispiece, and this handy book should soon become known to London students, and also to visitors from the Continent.

G. A. J. C.

NATURE STUDY FOR SCHOOL AND HOME.

(4) *Wild Life in the Woods and Streams.* By C. A. Palmer. Pp. xv+206. (London: A. and C. Black, 1914.) Price 3*s*. 6*d*.

(5) *The English Year: Summer.* By W. B. Thomas and A. K. Collett. Pp. viii+341. (London: T. C. and E. C. Jack, 1914.) Price 10*s*. 6*d*. net.

TO-DAY the junior student of biology has his attention directed to function and behaviour, rather than to those structural features which claimed almost exclusively the interest of

his predecessors of thirty years ago. This modern tendency is shown in the batch of books now before us.

(1) Mr. Furneaux, introducing his lesson-book for school-classes, tells us that his work "deals with living nature rather than with dead objects." Beginning with Amœba and the Yeast, he passes first to plant life, as illustrated by fern and flowering plant, and then to animal life, so far as it can be demonstrated by short lessons on butterfly, frog, pigeon, and a few common mammals. The grosser structure of flowering plants is discussed at some length; in the zoological section attention is directed chiefly to what may be seen by the pupils as they watch the living creatures. Indeed, the anatomical information is almost too meagre to be of use, and the classificatory schemes are faulty; for example, eagles and owls are placed in the same order of birds, while among the mammals the Ruminants are separated ordinally from the Ungulata, which are said to include the horse, ass, and swine! The book concludes with a chapter on human physiology extending to 25 pages. Distinctly useful as the book may prove to an earnest teacher, it leaves the impression of an attempt to include too much in the space allotted.

(2) Miss E. M. Goddard's book, "written to provide a course in elementary botany for the middle forms," and admittedly intended to be "useful to students preparing for examination," gives an excellent combination of practical exercises and clear explanations, illustrated by good, bold outline drawings. The pupil who works conscientiously through the physiological experiments, and laboratory and field observations described in this small volume will have won something better than examination successes—a well-grounded foundation for future study of plant life. On page 46 there is a curious slip of "corm" for "bulb," in a paragraph distinguishing these two favourites of the botanical examiner, which may puzzle the intending examinee.

(3) In "Pond Problems," Mr. E. E. Unwin has produced a noteworthy educational work. He deals only with aquatic insects, and no naturalist who appreciates the mode of treatment adopted will be surprised to find that the method of teaching was learned in the laboratory of Prof. L. C. Miall. Mr. Unwin has, indeed, given his fellow-teachers the benefit of his own lesson-notes. The nature of his method will best be realised from the fact that in 100 pages there are 397 questions, to most of which the pupils are left to find answers from their own observations. All the drawings and most of the photographic illustrations are excellent. Hints are given for the construction of simple but efficient pieces of apparatus, and the boys or girls who are fortunate enough to be taken through the course on the lines indicated will enjoy a "good time." Is it not a mistake to use the term "skin"—even with quotation marks and explanations—for the chitinous exoskeleton of an arthropod? Why not write "cuticle," and thus familiarise the student from the beginning with the essential difference between the secreted envelope and the true skin which forms it?

(4) With Mr. C. A. Palmer's contribution we pass from school-books to a play-book, for he has written a series of bright chatty notes on common animals in the form of letters to a young boy. Many of these are thrown into the anthropomorphic story-sketch which has been popular of late years, both in the United Kingdom and in America. The somewhat slight letterpress is illustrated by attractive drawings. Although the scene of "Dad's" zoological researches is ostensibly an English county, he describes and figures the trap-door nest of a Nemesia, which raises a certain degree of scepticism with regard to his other stories.

(5) Messrs. Thomas and Collett have produced a volume of popular natural history for the drawing-room, which in literary form, typographical finish, and illustrations is "a thing of beauty." The black and white sketches—drawn by Mr. A. W. Seaby—are mostly admirable, and there are some attractive reproductions in colour of notable landscapes, though a plain naturalist, with an old-fashioned preference for clear drawing, is grateful for the printed information that one of them represents "building the Rick"; "Digging out the Sand-pit" would have been equally credible as a title. The book is made up of a series of short chapters describing phases of country life through the months of June, July, and August. Animals and plants are discussed in relation to their surroundings, and the authors see birds and flowers with the artist's eye. The passion for the open so pervades the book that it will surely drive some readers "Along the River" and "Among the Grasses," if not "Below the Tidemark." In some of their explanations the authors are too dogmatic. Our British species of Erebia, for example, are not surviving members of "the Arctic fauna which flourished here in the Ice Age." They both belong to the distinctively Alpine group which is southern rather than northern in its affinity, and neither is to be found in the Arctic regions. The studies of bird and plant life are generally good, and the drawings of birds—at rest or in flight—are excellent, as are most of the plant sketches. In

the chapters devoted to insects, however, there are signs of want of touch between authors and artist. In the chapter on "Butterfly Flight" there is a drawing of a "Fritillary," which represents the plant, not the insect of that name; the "Little Blue resting," on p. 35, appears to have been drawn from a "Common Blue," while the "Female Emperor," on p. 104, is unmistakably *Arctia caia*, the "Common Tiger" moth. Such slips as these can, however, be easily rectified in a new edition.

G. H. C.

PRACTICAL DRAWING.

(1) *A Manual of Mechanical Drawing.* By J. H. Dales. Pp. xii+181. (Cambridge University Press, 1914.) Price 3s. net.

(2) *Machine Construction and Drawing.* Book ii. By A. E. Ingham. Pp. xii+180. (London: G. Routledge and Sons, Ltd., 1914.) Price 3s. net.

THE titles of these two books have been well chosen; in one the chief concern of the author is to ensure manipulative skill in instrumental *drawing*, and in the other to illustrate details of engineering *construction*.

(1) Those readers who take Mr. Dales as their guide will undergo a process of careful drilling in the use and maintenance of the scale, square, pencil, pen, and compass, by means of specially designed and carefully graduated sets of exercises, largely geometrical in character, followed by examples of the projection of various machine details, and completed by the preparation of a full set of working drawings of a screw-cutting lathe, fully dimensioned, with titles and descriptions, all executed in the style of the skilled professional draughtsman. Thus the book gives a course of organised training in the draughtsman's craft, valuable especially to students who afterwards enter a drawing office, for they will be ready to begin elementary design or other good work at once.

(2) Mr. Ingham has previously written an elementary book on the subject, and the present volume is intended as a continuation, suitable for more advanced students. It gives, with descriptions and simple calculations, a large number of well-selected examples representing modern engineering practice, arranged and classified in seven chapters headed respectively, "Power Transmission Appliances," "Gearing," "Steam Engines and Turbines," "Gas and Oil Engines," "Boilers and Fittings," "Machine Tools and Appliances," "Pumps and Compressors." The drawings are well printed and thoroughly workmanlike and have evidently been prepared by a highly qualified expert. The student's progress is tested from time to time by sets of suggestive examples in drawing, calculation, and design. The text-book is a very good example of its kind, and will give satisfaction wherever adopted.

OUR BOOKSHELF.

Essays and Addresses. By the late Prof. James Campbell Brown. Pp. x+208. (London: J. and A. Churchill, 1914.) Price 5s. net.

MR. HENRY H. BROWN, who edits this volume, explains in the preface that this selection of essays and addresses has been published because of the many requests for copies of particular papers by the late Prof. Brown which Mrs. Campbell Brown has received but was unable to accede to because most of the essays had never been printed.

The papers are arranged in chronological order, and most of them are concerned with various aspects of pure and applied chemistry. The first, on technical chemistry, was the chairman's address to the Liverpool section of the Society of Chemical Industry, and was delivered in November, 1886. The last essay, on science applied to the detection of crime, was an address to the chemical, physical, and legal societies at the University of Liverpool in 1908. The scope of the volume can be gathered from the titles of some of the other papers: the ethics of chemical manufacture, a French view of German industries, the use and abuse of hypothesis, and chemistry as a profession.

The papers have been printed as nearly as possible in the shape in which they were delivered, and will be welcomed by their author's old pupils and friends, who will recognise many characteristic touches.

The Happy Golfer. Being some Experiences, Reflections, and a few Deductions of a Wandering Player. By H. Leach. Pp. vii+414. (London: Macmillan and Co., Ltd., 1914.) Price 6s. net.

THIS is a brightly written book, full of the free air of the links and the sweet philosophy of the man who enjoys the simple life of the natural athlete. The author discovers in golf seven wonders, the fascination that grips, the traditions which never stale in the telling, the ubiquity of the game, St. Andrews the sacred Mecca of every golfing soul, the tragedy of the short putt, the three mighty men who share fifteen open championships among them, and the marvellous amateur eight times champion, and, lastly, the romance of the rubber-cored ball. On these as texts he dilates and prattles, then takes us all round the world searching for happy golfing hunting-grounds, returning finally to the best heaven-given links of the dear homeland. He talks of players and matches, of temperament and style, of courses and hazards. When he touches on what is generally called the science of the game he speaks wisely and not dogmatically. Not a single illustration of stance or grip disturbs the literary glamour of the page; and the mysteries

of the underspin and the dynamics of the slice and the pull are as if they were not. There is no "science" in the book; but it is admirably human.

C. G. K.

A History of the Teaching of Domestic Economy. Written for the Association of Teachers of Domestic Subjects in Great Britain by Ailsa Yoxall. Pp. 58. (London: Knapp, Drewett and Sons, Ltd., n.d.) Price 6*d.*

THIS little book represents the first attempt to place on record an account of the growth of the teaching of domestic economy in Great Britain. The movement appears to have been started in earnest about 1840, when some instruction in needlework began to be given in national schools for girls and infants. From this date to the present time the importance of instruction of this character has been recognised increasingly, until to-day the Association of Teachers in Domestic Subjects includes no fewer than thirteen important local branches, receives direct recognition by the Government, and elects one of its members to represent it on the Registration Council. The subject is now also given a more scientific character and includes a practical and theoretical study of every aspect of housewifery. The book deserves the attention of all who are interested in vocational education for girls.

LETTER TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Newton and the Spectrum.

IN NATURE of November 5, 1914, p. 263, I notice in the Astronomical Column a statement to the effect that, in connection with spectrum analysis, Wollaston (1802) was the first to employ the slit. I therefore venture to send a copy of the following passage, contributed by me to the 1913 Journal of the Leeds Astronomical Society, published last September:—

"Almost all writers, who quote Newton's classical experiment, overlook or ignore the fact that, recognising the impurity of the spectrum formed by admitting the sunlight through a round hole, Newton suggested the use of a linear aperture. Here is the passage from pp. 59–60 of the 4th edition of the *Opticks* (Book I., Prop. IV.):—

"'Yet instead of the Circular Hole, 'tis better to substitute an oblong Hole shaped like a long Parallelogram with its Length parallel to the [refracting edge of the] Prism. For if this Hole be an Inch or two long, and but a tenth or a twentieth Part of an Inch broad, or narrower; the Light of the Image will be as simple as before, or simpler, and the Image will become much broader, and therefore more fit to have Experiments try'd in its Light than before.'

"It is not quite clear whether Newton actually tried this narrow aperture. I think he did; and it is interesting to consider that, if he had sufficiently narrowed the slit, and observed the spectrum directly by the eye, instead of observing it upon a screen, he might have discovered the dark lines."

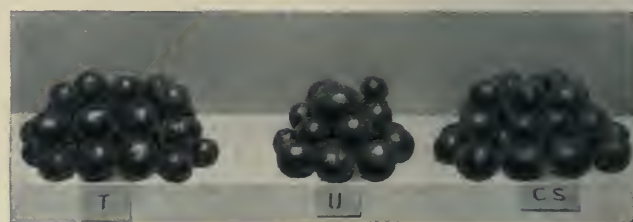
C. T. WHITMELL.

Invermay, Hyde Park, Leeds, November 9.

THE PARTIAL STERILISATION OF SOILS.

THE work to be described in this article arose, as so often happens, out of an accident in the laboratory. The writer was investigating the rate of oxidation of phosphorus, and during the progress of the work was called to take charge of an agricultural laboratory. Before finally disbanding the apparatus some observations were made on soils, and it was found that fertile soils absorbed oxygen more rapidly than non-fertile soils of the same character. Since the action was very considerably reduced in sterilised soils it was concluded that the process is largely due to

Untreated soil. Partially sterilised soils (by toluene). (by heat).



Partially sterilised soil (by toluene). Untreated soil. Partially sterilised soil (by carbon disulphide).

FIG. 1.—Crops grown on untreated and in partially sterilised soils.

the activity of micro-organisms, and the connection between oxygen absorption and fertility was attributed to the large part played by micro-organisms in the production of plant food.

In doing the final confirmatory set of experiments the soils were only sterilised at 100° and not at 130°, in consequence of a mistake which caused some little annoyance at the time. An experiment was, however, carried out with this partially sterilised soil, and it led to the remarkable result that oxygen absorption is more rapid in such soil than in normal untreated soil. Other methods of partial sterilisation gave the same result. In view of the close connection between

oxidation and productiveness, a set of pot experiments was put up, and these showed that the fertility of the soil was also increased after partial sterilisation. Typical results are illustrated in Fig. 1: the upper part gives experiments with rye, the lower part with tomatoes.

At this stage it was found that the fact had been discovered before by practical growers. Soil that had been heated, *e.g.* by a bonfire, or treated with the antiseptic (carbon disulphide) used for destroying certain pests, gave larger crops than before. The fact had even been reported to one or two of the German experiment stations, but it had not attracted very much attention. One important discovery had been made, however: it was found that partial sterilisation caused increases in the numbers of bacteria, and this was explained by supposing that the weaker races had been killed, leaving the more vigorous in clear possession of the field.

Systematic investigations at Rothamsted soon showed that the increased productiveness of partially sterilised soils was due to an increased formation of ammonia, and this in turn was traced to the increased numbers of bacteria. The new flora, however, was not composed of more vigorous races as had been supposed; on the contrary, it was less vigorous than the old, and it owed its extra decomposing power to its numerical superiority. This point was established by numerous experiments because of its great importance in explaining the phenomena. The reason for the increased bacterial numbers was traced to a detrimental factor present in normal soils and keeping down the bacterial numbers; this factor was put out of action by partial sterilisation, whereupon the bacterial numbers began to rise. Owing to its highly complex nature soil forms very unpromising material for a direct attack; investigations have nearly always to be indirect. In the present instance the method adopted for discovering the detrimental factor was to ascertain what agencies put it out of action and what did not, and thus to draw up a list of its properties. It was found, for example, that the detrimental factor was sharply put out of action by heating to 55° C., or by any poison, and that it never set up again so long as the soil was kept free from dust; it did, however, appear when a little untreated soil was added, but the reappearance was slow and somewhat erratic. These and other experiments all indicated that the factor was biological; but definite evidence was obtained that it was not bacterial. Suspicion therefore fell on the protozoa, which were found to occur in all the natural soils examined but to be killed by the partial sterilisation. A very large number of experiments showed that the destruction of the soil protozoa always went hand in hand with the increase in bacterial numbers; up to the present no exception has been found. This is strong presumptive evidence, but unexpected difficulties arose when attempts were made to clinch the evidence by inoculating mass cultures of protozoa into partially sterilised soils, and up to the present these have not been overcome. We are, therefore, thrown back on indirect methods.

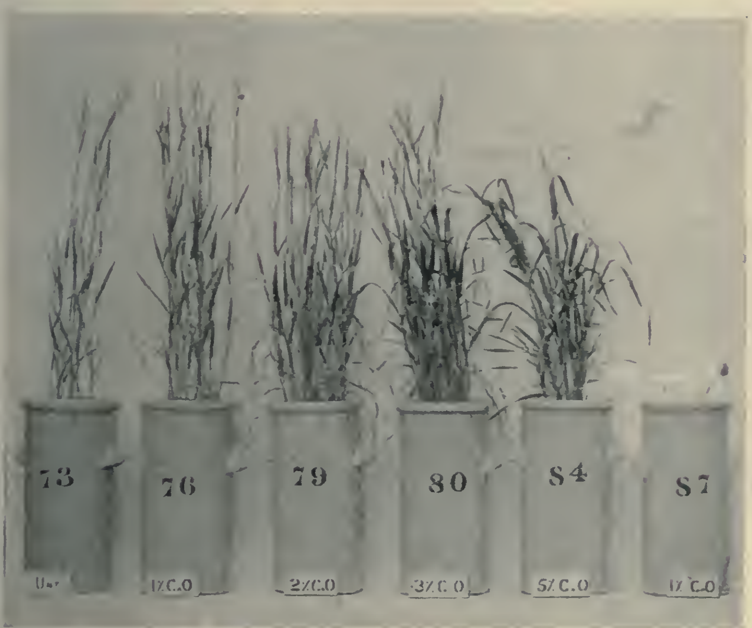


Fig. 2.—Lime as an agent for soil sterilisation. Pot 73, control; 76–87, successively increasing doses; between 79 and 80 lies the partial sterilisation point; 87 contains an excessive amount. (H. B. Hutchinson.)

The first difficulty that was raised against the identification of the detrimental factor with the soil protozoa was that the protozoa were probably present in the soil as cysts, and not in the trophic state. It was argued that the soil conditions must be unfavourable for the development of animals like protozoa, which stand in constant need of air and water. The first investigations seemed to support this view. The copious development of protozoa when untreated soil is inoculated into hay infusion, of course, proves nothing; and when attempts are made to entice anything out of the soil by thermo- or galvanotactic methods nothing happened. The test organism was *Colpoda cucullus,* a ciliate occurring abundantly in the culture and easy to pick out under the microscope, and no evidence could be obtained that it occurred in the trophic state in the soil.

However, the experiments were continued. Mr. Martin found that a film was formed when soil was vigorously shaken with concentrated picric acid solution which, on examination, was seen to contain protozoa. The significance of the observation is, of course, that the acid instantly kills the organisms in the soil, so that the state in

which they are found in the film is the state in which they actually occur in the soil. It was with no little interest, therefore, that the work of the protozoologists was watched, and when they discovered that the amœbæ were in the trophic state, and not all present as cysts, it was felt that a distinct advance had been made. Mr. Lewin has since devised a method of getting the protozoa alive out of the soil. Thus, satisfactory proof is furnished that an active protozoan fauna exists in normal field soils. Some of the organisms are of special zoological interest, and have therefore been studied in detail.

Even yet, however, the problem is not solved, because there is nothing to show how numerous the active protozoa are. Neither Martin's nor Lewin's method is susceptible of quantitative use, and at present the only guide is the ease with which the organisms can be picked out.

however, the main interest of the "sick" soils, *i.e.*, the soils known to be heavily stocked with the detrimental factor, is that they contain numerous active amœbæ, and never fail to give good crops of organisms by either of the methods in use.

On the other hand, the detrimental factor is reduced considerably by drying the soil, especially at high summer temperature. So also the harvest of protozoa becomes very thin in field soils during dry summer weather.

This, therefore, is the present position so far as the identification of the detrimental factor is concerned. There seems no doubt that it is living, and there is strong indirect evidence to connect it with the soil protozoa. But the direct evidence is lacking, partly because the difficulties of introducing mass cultures into partially sterilised soils have not yet been overcome, and partly because no satisfactory method of enumerating active protozoa in the soil has yet been devised. The zoological work is being continued: it has already more than justified itself by revealing the presence in natural soil of a trophic protozoan fauna the members of which are of considerable interest: the most important further development will be to ascertain whether the present indications are correct that the fauna is most numerous when the detrimental factor is most fully developed, and least numerous when the factor is not much in evidence.

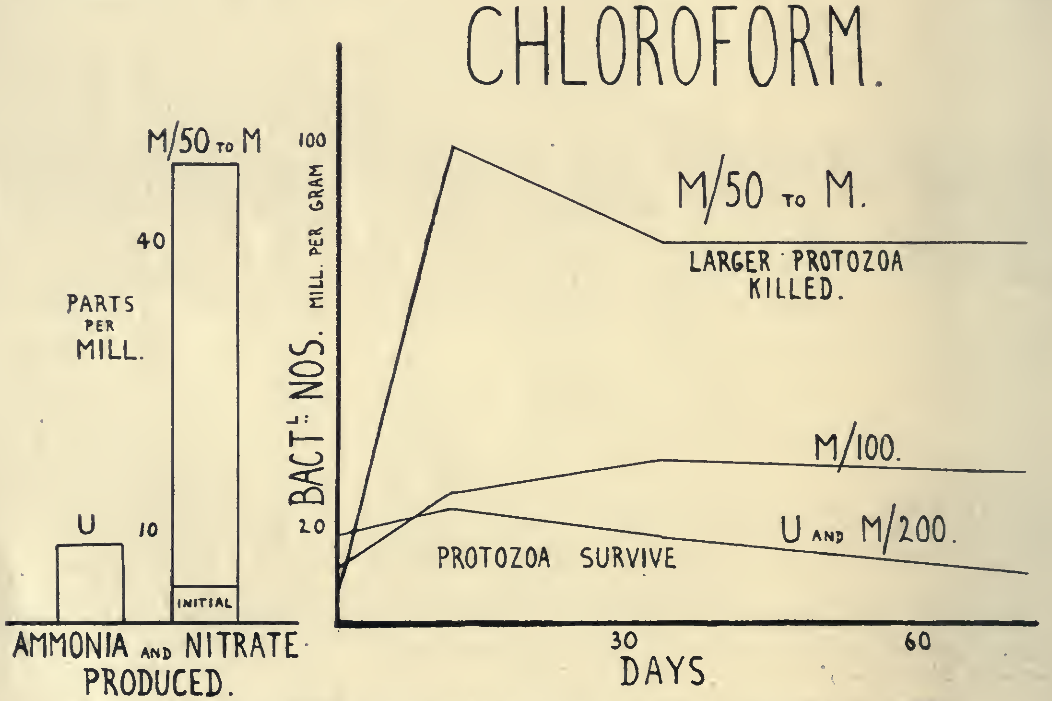

FIG. 3.—Effect of a typical volatile antiseptic on bacterial numbers and production of ammonia in soils. (Buddin.)

It was found from the soil investigations that the detrimental factor increased in intensity when the soil was kept moist, warm, and well supplied with organic matter. In these circumstances the bacteria might reasonably have been expected to increase enormously; as a matter of fact, they did not. Moreover, the fertility of these soils did not increase as much as was anticipated; it became less, and after a time no longer justified the cost of intense cultivation: this fact is well known among nurserymen, who speak of such soils as "sick." The treatment in the past has been to throw the soils out in despair, and to sacrifice the great manurial residues they contain. But it was obvious that the proper course was to adopt partial sterilisation methods; and laboratory and pot culture experiments alike proved the success of the method. For the moment,

The "sick" soils mentioned above are so important from the technical point of view that they have been further investigated. Sickness is proved to be an excessive development of the detrimental factor and also of disease organisms. The demonstration that it could be cured by

partial sterilisation aroused much interest among nurserymen and growers who forthwith arranged to have trials made in their own glasshouses. The first efforts were, of course, crude; methods that work satisfactorily in a laboratory with a few kilos of material have a way of breaking down hopelessly when it comes to handling hundreds of tons in a commercial nursery. But the second season saw a great improvement, and the third an even greater, while perhaps the most satisfactory result of all is that the growers have collected 2500*l.*, half among themselves and half from the Development Fund, wherewith to build an experiment station to attack the special problems of their industry, and they have also obtained for it an income of some 900*l.* a year for the working expenses.

stances, and finds a fundamental distinction between volatile and non-volatile organic antiseptics, illustrated in Figs. 3 and 4. Volatile compounds partially sterilise and then disappear, leaving no traces behind them: the effect on the soil depends solely on the germicidal potency of the substance. Non-volatile compounds, on the other hand, remain in the soil and react both on the organisms and the plant, but their action on the bacteria is peculiar. So long as the doses are not too strong, some of the soil bacteria flourish and multiply to an astonishing degree, apparently feeding on the antiseptic: phenol, cresol, hydroquinone, quinone, are all among the unpromising substances that produce this effect. The phenomena are quite distinct from those observed with volatile antiseptics; the rise in bacterial numbers

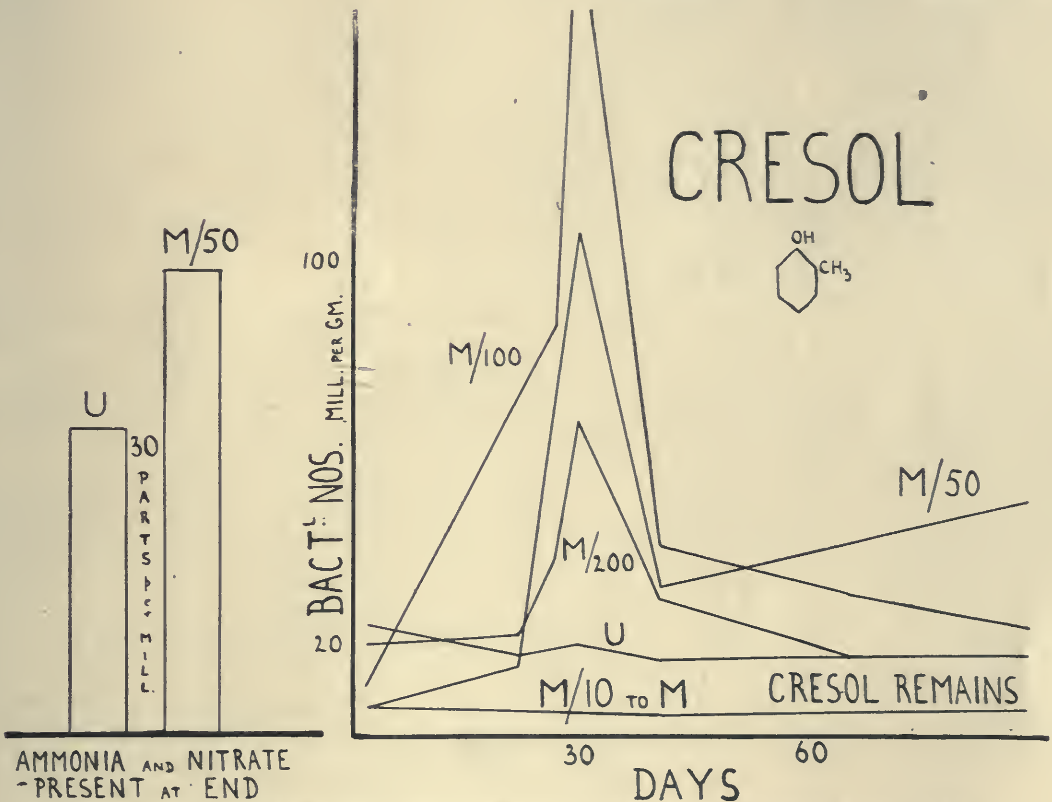

FIG. 4.—Effect of a typical non-volatile antiseptic on bacterial numbers and production of ammonia in soils. (Buddin.)

At present nurserymen use steam, but this would not be applicable for ordinary field work. The volatile antiseptics which work so well in the laboratory have also proved ineffective, even if the difficulties of application could be overcome. Search has therefore been made among solid and non-volatile liquid antiseptics. Lime was investigated by Dr. Hutchinson and found to answer satisfactorily; small doses are absorbed by the soil, but after a certain saturation point is reached the excess remains free and partially sterilises. All the usual phenomena turn up together, and the point indicated by the chemical tests is found to agree closely with that found by bacteriological and plant-growth tests (Fig. 2). Mr. Buddin has tried a wider range of sub-

is much higher, but it is not sustained; there is no sharp connection between the bacterial increase and the death of the protozoa, and the increased bacterial numbers do not produce any corresponding increase in ammonia or nitrate. Hence these non-volatile organic substances do not appear very promising, and for the moment steam remains the best agent: it partially sterilises; it effects some decomposition of the soil organic matter, and so lightens the subsequent work of the bacteria; and it produces some substances which induce a remarkable development of fibrous root. Experiments are still in hand, and we hope eventually to learn sufficient about these effects to be able to reproduce them in a way applicable to field conditions.

E. J. RUSSELL.

THE FAR-NORTH AUSTRALIAN.[1]

THE three volumes of studies of the natives of Central Australia which were published by Prof. Baldwin Spencer and the late Mr. F. J. Gillen, required for their completion some account of the natives of that portion of the continent which stretches northward to the shores of the Arafura Sea. This natural sequel, an account of the people of the Northern Territory, is to be found in the new and valuable record, dedicated to the memory of his dead colleague, which has just been written by Prof. Spencer. With the experience gained in his previous investigations, the author has produced an excellent volume, which is in every way equal to its forerunners in anthropological interest, in scientific value, and in clear description of another group of the totally uncivilised tribes of Australia.

FIG. 1.—Two Kakadu Men. From "Native Tribes of the Northern Territory of Australia."

The introductory chapter, aided by nearly thirty pictures, gives a particularly vivid description of the country occupied by the tribes, their appearance and dwellings, general way of living, character and mental ability. A map shows the location of the tribes, those dealt with in most detail being resident on Melville and Bathurst Islands, on the mainland about Port Essington, the Alligator Rivers and Port Darwin, and southward to the region between Victoria River on the west and Roper River on the east. The total population is estimated at about 50,000.

The social organisation most prevalent in this region was found to differ from that usual in other parts of Australia. Instead of the class organisation, in which the tribe is divided into two main divisions, each with its subdivisions regulating marriage, and with descent either in the male or female line, many of the northern tribes follow a local organisation. The people are divided into a series of local groups, each owning and occupying a special district, and on marriage a man of one group takes his wife from another, and brings her and his children into his own group. The details of the various systems are fully given by Prof. Spencer, with tables of relationship terms in a series of typical tribes, and also the status terms applied to individuals at different periods of life.

With respect to the initiation ceremonies, the author divides the northern people into three groups. The first, occupying the islands, Coburg peninsula, and adjacent mainland, practise neither circumcision nor subincision. Adjacent tribes on the south practise circumcision only, whilst others inland from the coastal ranges and towards the centre of the continent practise both circumcision and subincision.

There is much variation in the totemic systems of the tribes. Where there is class organisation the totem groups are variously divided. Exogamy, though usual, is not always strict. Where the local organisation prevails, though there may be some marriage restrictions, there is sometimes no question of descent involved, and a child's totem is revealed to the father in a dream. The totems in all the tribes are usually edible articles, animal or vegetable, but in some cases implements and natural objects are totems. In many of the tribes a man may not eat his totem, but in others,

FIG. 2.—Placing the Bull-roarer on the hands of the Initiates, Larakia Tribe. From "Native Tribes of the Northern Territory of Australia."

[1] "Native Tribes of the Northern Territory of Australia." By Prof. Baldwin Spencer. Pp. xx+516. (London: Macmillan and Co., Ltd., 1914) Price 21s. net.

though he may not capture or gather it, he may eat it if it be given to him by a man of another group. For the purpose of increasing the supply of the totemic animal or plant, certain magical ceremonies are performed. The bull-roarer and other sacred objects so prominent in the central region was not found among the tribes of the islands, the Coburg peninsula, and coast southward. The Kakadu (Alligator River) call the bull-roarer *kumali* and the Larakia (Port Darwin) *bidubidu*. The ceremonies in which they are used, and the traditions regarding them, are described by Prof. Spencer. Burial and mourning ceremonies vary greatly. The Melville islanders bury their dead in graves with elaborately ornamented grave-posts. The Kakadu of Alligator River also bury in the ground, but other tribes place the body in a tree. The Larakia follow tree-burial by burial in the earth or in holes in rocks. The Mara tribe eat their dead, and after exposing the bones on a tree platform, bury all but the long bones of the arm.

An interesting account is given of magic and medicine. Evil is wrought by burning excrement. This entices away a man's protecting spirit, and so renders him liable to accident or hunger. The same practice will give a strong man's power to a youth. Maleficent magic is also wrought with a fragment of the victim's food, or with mud scraped from his foot. Disease is cured by eating pounded ant-hill.

The author discusses the curious belief as to the origin of children which, as in Central Australia, is found also among the northern tribes. The far-off ancestors, as they travelled about, shook off spirit children into caves and trees. These enter the women at these places and are born as natives. The dead go back to their old home, and after a time are born again, the sex being changed at each new birth. Half-castes are the result of eating the white man's flour.

Two extremely interesting chapters are devoted to traditions and legends. Food restrictions are also dealt with. They show the natives specially hampered by definite rules of eating during child-bearing and youth, age being privileged.

Separate chapters describe the weapons and implements, clothing and ornaments, and decorative art, the latter including rock and bark drawings. The illustrations to these chapters, some coloured, show these northern natives to be more advanced artistically than other Australians.

FIG. 3.—Scene from the Muraiin Ceremony, Kakadu Tribe. From "Native Tribes of the Northern Territory of Australia.

There is no suggestion of Malay influence in the region, and the author gives reasons against its possibility. The valuable linguistic appendix, mainly relating to three tribes, shows the languages to be characteristically Australian.

A few inconsistencies and omissions may be noted. The Umbia and Bingongina of p. 483 appear as Umbaia (p. 7, 17), Binbinga (p. 7). The organisation of the Maluuru tribe is given (p. 56), but there is no indication of its locale or that of the Allana tribe (p. 483). The use of Austral-English appears in the use of such words as: goanna, sugar-bag, lubra, pitchi, wurley, miamia, billy, biliabong, tuck-out, and tucker.

Special features of the volume are the number and quality of the illustrations. There is a good index.

The work is an exceedingly valuable contribution to anthropological literature, indispensable for the student of primitive beliefs and ceremonial.

Sidney H. Ray.

THE EVOLUTION OF THE PETROGRAPHICAL MICROSCOPE.

When Henry Clifton Sorby laid the foundation of the science of microscopical petrology, in the year 1851, the instrumental means at his command were of the simplest kind; his microscope had attached to it two Nicol-prisms, one above the eye-piece and the other below the stage, the latter being capable of rotation, thus rendering it possible to study the sections of minerals in rocks by plane polarised light. Then, as is so often the case, necessity became "the mother of invention," and Sorby himself, as well as several of his followers, devised additions to their microscopes which converted them into more useful instruments for investigating the optical properties of minerals, as seen in thin sections of rocks. The designers of these improvements were, of course, dependent on the able makers of optical instruments for putting their suggestions into practical form.

In the year 1876 the late Prof. Rosenbusch, of Heidelberg, who had been led to the microscopical study of rocks by Heinrich Fischer, one of the earliest pioneers in this branch of research in Germany, described "a new microscope for mineralogical and petrological researches." The chief features in this microscope were an accurately graduated, revolving stage, with verniers, and a complex nose-piece enabling the objectives to be rapidly changed. About the same time MM. Fouqué and Michel Lévy—with the co-operation of M. Emile Bertrand—had also turned their attention to the improvement of this class of instruments. The eminent optical instrument-maker of Paris, M. A. Nachet, carrying out their designs, constructed a microscope which embodied many advantageous features for petrographical work. In this instrument the necessity for the troublesome centring arrangements, for keeping an object on the cross-wires of the field of view, is got rid of by dividing the tube into two portions moving independently, the upper section carrying the eye-piece, analyser, and some accessory apparatus, and the lower attached to the finely graduated revolving stage bearing the objectives; these latter are easily changed by moving in a slide with spring-catch. Another important addition to the instrument which we owe to the French petrologists is the series of converging lenses with a magnifying lens above, by which interference figures may be viewed in the thin sections of minerals in rock-slides. It is true that these interference figures are only partial ones, but by the aid of diagrams supplied by the authors of the method their interpretation is rendered possible.

Outside France, the Nachet instrument would not appear to have come into very general use, a fact which is perhaps accounted for by the rather cumbrous arrangements necessitated by the division of the tube. In this country an arrangement having the same object has been devised by Mr. A. B. Dick, and has found much favour with many petrologists. It consists in having the rotating, polarising and analysing prisms so connected that they can revolve together, while the stage is fixed. The forms of the ordinary and Dick types of petrographical microscope, as employed by the officers of the Geological Survey of Great Britain are illustrated in Figs. 1 and 2.

Still more recently the celebrated Russian crystallographer, Féderow, has devised a form of the mineralogical and petrographical microscope, in which the crystal or section to be examined is carried on a stage which is capable of movement and inclination at exactly measurable angles, by which means very important optical determinations may be made. Instruments constructed on Féderow's plan are made by the Société Genevoise pour la Construction d'Instruments de Physique et de Mécanique, 87 Victoria Street, London, S.W.

As a matter of course, all the improvements in the mechanical and optical arrangements in microscopes introduced during the last fifty years have been made available for the instruments constructed for mineralogical and petrographical work. With the addition of many pieces of accessory apparatus, such as sections and wedges cut in definite directions from the crystals of various minerals, stage goniometers, and special arrangements for stage-movement, the instruments of this class have now become, as will be seen from the figures, more and more complicated as the refinement of methods has increased.

Not less important than these elaborate instruments employed in research are the simpler forms used in elementary and advanced geological teaching, which must necessarily be produced at much smaller cost. There are also special petrographical microscopes made, which are adapted for projection purposes in lecture-theatres, for photographic work, for examining crystals and sections while being heated and cooled, and for studying the development of crystals in solutions and fused materials. Examples of many of the types of petrographical microscopes are exhibited in the Science Museum at South Kensington.

As a direct offspring of the petrographical microscope, we may refer to the instruments now so extensively employed in metallographical researches. In 1864 Sorby, while studying sections of meteorites, for the purpose of comparing them with terrestrial rocks, was led to examine the grains of nickel-iron in the "sporado-siderites," after they had been etched, by reflected light. It occurred to Sorby that the same method of study might with advantage be employed in the case

of artificial irons and steels, and his residence at Sheffield enabled him to obtain the necessary materals for a research, which not only resulted in important discoveries by himself, but laid the foundation of the science of microscopic metallography, which has made such important advances in recent years.

Our illustrations are taken from the catalogue of Messrs. James Swift and Son, who in this country have been among the foremost in meet-

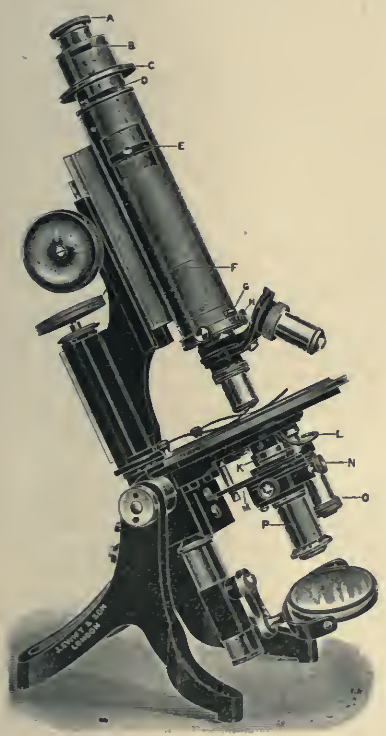

FIG. 1.—Swift's "Survey" Petrological Microscope. A, Rotating analyser working over ocular; B, slot for quartz wedge or other compensator; C, divided circle working in conjunction with analyser A; D, slot through ocular for micrometer, etc.; E, slide carrying upper Bertrand lens which can be focussed and pushed out of the optic axis when not required; F, analyser in body, instantly removable from optic axis; G, slot for quartz wedge, etc., when working with analyser F; H, centring nosepiece; J, achromatic convergent system; K, iris diaphragm; L, loop for instantly removing top hemispherical lens of condenser; M, swing-out rotating cell for stops, compensators, etc.; N, centring screws to convergent system; O, focussing adjustment for convergent system; P, polariser mounted on independent swing-out arm.

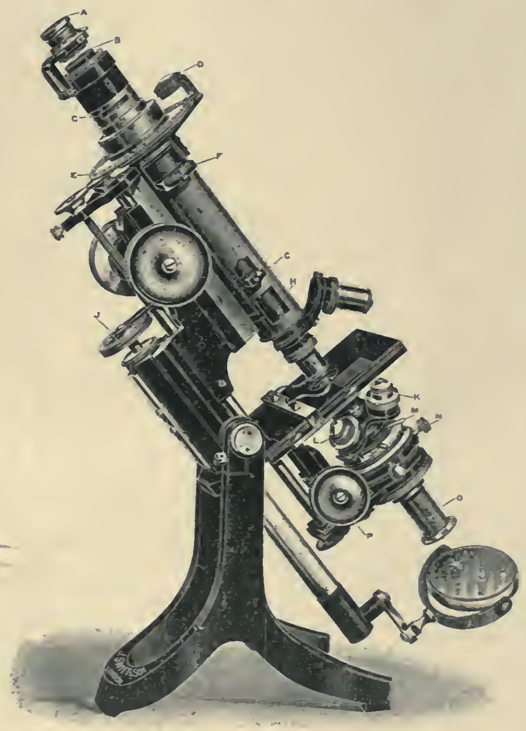

FIG. 2.—Swift's "Improved Dick" Petrological Microscope (Khartum model). A, Analyser mounted above ocular and geared to rotate simultaneously with the polariser; B, cross-webbed ocular; C, slot through ocular for wedges, micrometer, etc.; D, lens for reading circle and vernier; E, divided circle reading by vernier to 5′; F, slide bearing Bertrand lens (this lens is provided with a diaphragm of apertures and can be focussed and pushed out of the optic axis when not required); G, slide bearing lower Bertrand lens, Klein's quartz plate and a clear aperture (this lower Bertrand lens shows a much larger interference figure than the upper one, filling as it does the entire field of the ocular); H, extra analyser mounted in body (this analyser is generally used for photomicrography); J, fine adjustment by differential screw which by means of a vernier reads to 0·0002 mm.; K, aplanatic oil immersion condenser, n.a. 1·40; L, aplanatic dry condenser, n.a. 1·0; M, iris diaphragm below which is a rotating swing-out cell for stops, compensators, etc.; N, screws to centre condensers; O, polariser mounted on an independent swing-out arm; P, milled head for focussing condensers.

ing the often difficult requirements of scientific men, by carrying out their suggestions with great practical knowledge and skill. J. W. J.

DR. M. C. COOKE.

BOTANISTS will learn with regret of the death of the veteran mycologist, Dr. M. C. Cooke, at Southsea on November 12. Mordecai Cubitt Cooke was born at Horning, Norfolk, on July 12, 1825. His early education was scanty, but he received help from his uncle, who instructed him in botany as well as in mathematics and languages. Some years later he became a lawyer's clerk, and afterwards a teacher under the old National School system, the economic value of food-plants being one of his teaching subjects. This led to his preparation of a catalogue for the Indian Department of the Exhibition of 1862, and eventually to work at the India Museum. Here he spent much time studying the lower cryptogams, especially fungi, on which he soon became a leading authority.

In 1880 Cooke obtained an appointment in the Herbarium of the Royal Botanic Gardens, Kew, being placed in charge of the Thallophyta, a post which he continued to hold until he retired at the age of sixty-five. Whilst at Kew he completely re-arranged the mycological collections, and incorporated the large and valuable herbarium of the Rev. M. J. Berkeley, and later on his own extensive collections, which have been estimated to number 46,000 specimens. He also dealt with material coming in from abroad, from which he described and figured many new species. During this period he was assisted in his private work by Mr. George Massee, who afterwards succeeded him in his duties in the Cryptogamic Department.

Cooke stands out as a great systematic mycologist, and as a populariser of his science. His first important work—"Handbook of British Fungi"—(1871) is a classic, which to this day demands a good price. The most celebrated is "Illustrations of British Fungi." These eight volumes, containing 1200 plates of British Agaricaceæ, are a stand-by of all British mycologists, and the fact that they are still the subject of scrutiny and criticism by eminent continental botanists only testifies to their importance in mycological literature. For twenty years Cooke edited *Grevillea*, a journal devoted to

Cryptogamic botany. He also published a fungus flora of Australia and many papers of scientific importance, besides innumerable minor articles. His industry is further attested by the presence in the Kew collections of about 25,000 of his drawings of fungi. During later years, especially, he wrote popular books, and also turned his attention to other fields of cryptogamic botany.

After his retirement in 1892 Cooke retained his interest in fungi, and until 1904 attended the annual fungus foray of the Essex Field Club. Recently his eyesight failed, though his mind remained keen and active. He was honorary M.A. of Yale, and LL.D., and in 1903 he had the honour of being awarded the gold medal of the Linnean Society. A. D. C.

NOTES.

THE King has been pleased to approve of the following awards this year by the president and council of the Royal Society:—A Royal medal to Prof. E. W. Brown, F.R.S., for his investigations in astronomy, chiefly in lunar theory; a Royal medal to Prof. W. J. Sollas, F.R.S., for his researches in palæontology, especially in the development of new methods. The following awards have also been made by the president and council:—The Copley medal to Sir Joseph Thomson, O.M., F.R.S., for his discoveries in physical science; the Rumford medal to the Rt. Hon. the Lord Rayleigh, O.M., F.R.S., for his numerous researches in optics; the Davy medal to Prof. W. J. Pope, F.R.S., for his researches on stereochemistry and on the relations between crystalline form and chemical constitution; the Darwin medal to Prof. E. B. Poulton, F.R.S., for his researches in heredity; the Hughes medal to Prof. J. S. Townsend, F.R.S., for his researches on electric behaviour of gases.

NATIONAL regret at the death of Lord Roberts on Saturday last, as the result of a chill caught while on a visit to France to see the Indian troops, is shared by men of science. Throughout his career Lord Roberts stood for scientific organisation and individual efficiency; and to the last day of his life he was concerned with undertaking useful services for his country. In the field his success was the fruit of careful forethought, boldness, and vigour; when an administrator he laid stress on the encouragement of intelligence and initiative among soldiers of all ranks; and after his retirement from active service he devoted the remainder of his days to advocating the encouragement of rifle shooting as a national pursuit, and the establishment of a system of obligatory physical training. He saw the needs of his country and did his best to educate public opinion in favour of a remedy for them. In Lord Roberts the attributes of duty and self-sacrifice were represented at their highest, and the whole Empire mourns that he has now passed into silence.

THE council of the Physical Society of London has decided not to hold the annual exhibition of physical apparatus this year.

THE eighty-ninth Christmas course of juvenile lectures, founded at the Royal Institution in 1826 by Michael Faraday, will be delivered this year by Prof. C. V. Boys, his title being "Science in the Home."

WE regret to learn of the death, at sixty-five years of age, of Dr. J. Borgmann, professor of physics in the University of Petrograd, and author of various works on electricity and magnetism.

WE regret to announce that Prof. August Weismann, professor of zoology in the University of Freiburg-im-Breisgau since 1867, foreign member of the Royal Society, and of world-wide distinction as a biologist, died on November 5 at eighty years of age.

AT the annual meeting of the London Mathematical Society, held on November 12, the De Morgan medal was presented to Sir Joseph Larmor in recognition of his researches in mathematics and mathematical physics.

A FAIRLY strong earthquake was felt over Jamaica on October 15 (see NATURE, vol. xciv., p. 207). A month later, on November 15, two other shocks were felt, the first at 12.50 a.m., of considerable force, and lasting seven or eight seconds; the second, a slighter shock, between 8 and 9 a.m. No serious damage was caused by either shock.

MR. W. S. ADAMS, Mount Wilson Solar Observatory, California; Prof. H. Andoyer, professor of physical astronomy in the Sorbonne, Paris; and Dr. F. Schlesinger, director of the Allegheny Observatory, and professor of astronomy, University of Pittsburgh, U.S.A., have been elected associates of the Royal Astronomical Society.

IT is announced in the *London Gazette* that the King has appointed Mr. T. H. Warren, president of Magdalen College, Oxford, to be Knight Commander of the Royal Victorian Order, and Mr. C. G. Robertson, fellow of All Souls' College, and senior tutor in modern history at Magdalen College, Oxford, to be Commander.

FOR several years Prof. W. B. Bottomley, King's College, London, has been working on the bacterial treatment of peat; and some results of the investigation have been described in papers presented to the Royal Society and the British Association. The Board of Agriculture has now made a grant of 150*l*. to the botanical department of King's College in aid of research on the subject of the probable accessory food-substances in humus and "bacterised" peat, a condition of the grant being "that reasonable facilities will be accorded to any accredited scientific worker who may desire to undertake investigations in connection with 'bacterised' peat."

AT the anniversary meeting of the Mineralogical Society, held on November 10, the following officers and members of council were elected:—*President*: Dr. A. E. H. Tutton. *Vice-Presidents*: Prof. H. L. Bowman and Dr. A. Hutchinson. *Treasurer*: Sir William P. Beale, Bart. *General Secretary*: Dr. G. T. Prior. *Foreign Secretary*: Prof. W. W. Watts. *Editor of the Journal*: Mr. L. J. Spencer. *Ordinary Members of Council*: Mr. F. H. Butler, Mr. J. P. De Castro, Mr. B. Kitto, Prof. A. Liversidge, Dr. J. J. Harris

Teall, Mr. F. N. Ashcroft, Prof. H. Hilton, Mr. A. Russell, Mr. W. Campbell Smith, Dr. J. W. Evans, Dr. F. H. Hatch, and Mr. J. A. Howe.

At a meeting of the council of the British Association, held on November 6, it was resolved:—"That the council of the British Association for the Advancement of Science, at its first meeting in London since the return of members from Australia, desires to place on record its high appreciation of the generous reception given to the members of the overseas party throughout the Commonwealth by representatives of the Governments of the Commonwealth and the States, and by other authorities and Australian citizens generally, on the occasion of the meeting of the association in Australia in 1914. The council hereby expresses its grateful thanks for the hospitality, privileges, and concessions extended so freely to visiting members, and also for the willing and valuable collaboration of all those who undertook so successfully the work of organisation in Australia in connection with the meeting."

By the death of Sir Walter Gilbey at Elsenham Hall, his Essex residence, on November 12, the country is distinctly the poorer, as the deceased baronet had an unsurpassed practical knowledge of horses and horse-breeding, more especially as regards "shires," hackneys, and ponies. His two little books on these breeds are models of what such works should be, teeming, as they are, with practical and historical information condensed into the briefest possible space. Sir Walter was the founder of the Shire Horse Society, which published its first stud-book in 1880, and held its first show at the Agricultural Hall in 1881. He also took an active part in the establishment of both the Hackney Horse Society and the Hunters' Improvement Society, and he was likewise instrumental in diverting the grants for "Queen's Plates" to the more useful purpose of premiums for thoroughbred sires. He was in turn president of both the Shire Horse and the Hunters' Improvement Society. It may be added that Sir Walter did no less good service for stock-breeding and agriculture in general. He had attained the ripe age of eighty-three years.

America has lost one of her leading geographers by the death, in his sixty-ninth year, of Mr. Henry Gannett. After graduating at the Harvard Scientific and Mining Schools, he was for a short time an assistant at the Harvard Observatory. From 1872 to 1879 he acted as topographer for the Hayden Survey of the Territories. When the U.S. Bureau of Geological Survey was established in 1879, Mr. Gannett assisted in planning out its work, and from 1882 until his death he held the position of its chief geographer. He was geographer to three decennial censuses and to the Conservation Commission of 1908–9, chairman of the U.S. Geographical Board, and president of the National Geographic Society. His published works included gazetteers of twelve States, the statistical atlases of three censuses, the contour map of the United States, a manual of topographic surveying, and numerous official reports. In an editorial note on his career the New York *Evening Post* pays him the tribute that, in spite of the notable results of his own industry, it is as a stimulator of other geographers and map-makers that he chiefly deserves to be remembered.

We are glad to see again the familiar pages of the *Revue Scientifique*, the publication of which was suspended at the beginning of August, on account of the war. The number which has just reached us is the first to be published since August 1, and it bears the date August 8–November 14. The main part of the issue is made up of the papers upon the nature and treatment of wounds, presented to the Paris Academy of Sciences on August 10 and September 28, and referred to already in our columns. Following these is a translation of the statement signed by German professors as to the cause of the war, with a complete list of signatures, and replies to the manifesto made by the Academy of Sciences, the French Academy, Institute of France, representatives of Russian art, literature, and science, and British scholars. Sir William Ramsay's article on "Germany's Aims and Ambitions" is translated from Nature of October 8, and there is also a translation of the letter from Dr. C. W. Eliot, president of Harvard University, published in the *New York Times* of October 2. We trust that our contemporary will find it possible to continue its weekly issue as formerly. *La Nature*, which suspended publication on August 1, has not yet started a re-issue.

Accounts of the valuable work which the officers of the Royal Army Medical Corps have accomplished in Boulogne for our wounded are given in the *Times* of November 10 and 14. The description of the Boulogne hospitals affords a clear picture of the very best sort of hospital administration and practice, thanks to Colonel Lynden Bell, Sir Almroth Wright, and all members of the staff and nursing staff of each hospital. From the potent and unfamiliar infections of the Belgian soil, which has been under intensive cultivation and incessant manuring for a quarter of a century, comes a host of troubles. The majority of the wounds are contaminated at the moment of infliction. The usual ritual of the antiseptic and aseptic method, perfect in time of peace for this or that formal operation of surgery in a placid, well-appointed hospital, may not suffice for the treatment of men wounded in the trenches by shrapnel or shell fragments, their clothes and their skins caked thick with mud, and that mud carrying dangers of its own. Against the risk of tetanus, we have the protective use of the tetanus antitoxin; against gangrene, we have the injections of oxygenated water, and the later "open-air" treatment of the wound, and there are other methods by which science is used to reduce suffering at the Boulogne hospital base and elsewhere.

In *Man* for November, Prof. Carveth Read examines the question of the differentiation of man from the anthropoids. He dwells on the importance of the change from a vegetable to a carnivorous diet on the habits, functions, and structure which distinguish man from the higher apes. This change of diet, he urges, explains the adaptation of our species to a ground-life and to a world-wide diffusion. This in-

volves social co-operation, the growth of articulate speech, the invention of weapons, and the discovery of the use of fire. Again, it involves the growth of the erect gait and of other modifications in the bodily structure. He urges that if this hypothesis be not accepted, man is an exception to the rule of animal life—that the structure of every organism is made up of apparatus subserving its special conditions of nutrition and reproduction.

WITH part viii. of his useful periodical, *Visvakarma* Mr. A. K. Coomaraswamy has for the present suspended its publication. The work contains one hundred examples of Indian architecture, sculpture, painting, and handicrafts. Mr. Eric Gill supplies a rather flamboyant introduction. The nineteenth century, he tells us, "for all its hard-headedness, was soft-hearted and loose-thinking." The newly awakened interest in Oriental art is, he thinks, "a genuine reaction against the irreligious gentility and banality of modern European art." There is some excuse for this acrid criticism, and *Visvakarma* helps to show that the art of India has much to interest the European student. But the cause of Oriental art will scarcely be promoted by disparagement of the aims and methods of European artists.

MESSRS. C. A. Hall and Duncan Smith have reprinted from the Transactions of the Paisley Philosophical Institution, 1914, a paper dealing with the geological and historical significance of some hazel nuts and other plant remains discovered during excavations at Paisley Abbey in March, 1914. These remains rested on the gravel of an ancient sea-beach, which is believed to be the 25-ft. raised beach, a pronounced feature in various parts of the Clyde area. This, after attaining its maximum elevation, was depressed and submerged. When hazel trees grew in this area it was some 25 ft. lower than it is at present. The writers, associating Neolithic man with the 25-ft. raised beach period, urge that their investigation forms a fresh link in the chain of evidence by which the age of Neolithic man may be determined.

A CLASS in mineralogy, with free access to a representative series of specimens, is the latest development of the Children's Museum, Bedford Park, Brooklyn. The collection of minerals, according to the November number of the *Children's Museum News*, has also been rearranged and expanded, economic uses being the basis of classification.

"THE Middle Triassic Marine Invertebrate Faunas of North America" is the title of a very fully illustrated memoir by Prof. J. Perrin Smith, published in Washington by the Department of the Interior (U.S. Geological Survey) as Professional Paper No. 83. It deals chiefly with cephalopods, especially ceratites and other ammonoid groups, 142 out of the 148 pages of letterpress being devoted to that class. In Triassic times the sea, which had previously covered large portions of the area now occupied by the North American continent, had retreated westwards until it formed only a gulf in the region of the Great Basin. The most remarkable feature of the fauna of the Middle Triassic beds of this tract is its complete lack of relationship to that of Japan, and its marked affinity to that of south-eastern Europe. It is, in fact, of "such a distinctly Mediterranean character that if a palæontologist from Austria were set down in the Triassic area of the Humboldt desert he could hardly tell from the character of the fauna whether he was collecting in Bosnia or in Nevada."

PROF. PERRIN SMITH's work on the Triassic ammonoids referred to in the preceding paragraph was doubtless the forerunner of a paper on accelerated development in fossil cephalopods, issued in the Leland Stanford Junior University Publications, University Series, for 1914. To do justice to this thoughtful communication would take much more space than is at our disposal; and it must suffice to state that, owing to the compression of the earlier stages, a large number of groups do not exhibit a recapitulation of their ontogenetic history. There is, in fact, a constant loss of stages or characters, which become pushed back and finally crowded out of the ontogeny, all along the race-history, so that successive types do not exhibit their full genealogical story. In addition is "convergence," which, in ammonites, has rendered a number of types descended from perfectly distinct ancestors so alike as totally to defy recognition of their genealogy.

MR. FREDERICK CHAPMAN provides a comprehensive review of the Cainozoic strata of Australia in the fifth memoir of the National Museum, Melbourne (July, 1914). He shows that the supposed nummulites of Australia should be referred to Amphistegina, and regards the earliest beds of what he calls "the Australian Cainozoic system" as of Oligocene age. The correlation of the strata with those of Europe, and the description of typical sections, make this paper especially welcome.

THE inspiring story of the rise and progress of the Scottish school of geology was selected by Prof. T. J. Jehu as the subject of his inaugural lecture as Murchison professor of geology and mineralogy in the University of Edinburgh. Due stress was laid in this discourse on the influence of Sir Andrew Ramsay, T. F. Jameson, Sir Arch. Geikie, also Prof. J. Geikie and other Scottish workers, in promoting a just appreciation of glacial phenomena in our islands.

PROF. GÜRICH, of Hamburg, has published (Borntraeger, Berlin, price 5.50 marks) an illustrated account of "Die geologischen Naturdenkmäler des Riesengebirges," which forms a scientific guide to a region of granite tors and ice-worn hollows which has been little visited by strangers. The fine view of the Schistose Schneekoppe (1605 miles) reminds us of our own highlands, where the cirques are becoming modified by downwash and general decay. A block of orbicular granite is figured, which is probably of local origin. This, like other natural monuments in the district, has been put under special guardianship.

ONE of the most interesting and readable memoirs issued in the Clare Island Survey series is by T. Hallissy on the geology of the island (Proc. Royal

Irish Academy, vol. xxxi., part 7, price 1s. 6d.). Reference is made for further details to the memoir recently published by the Geological Survey of Ireland; but the present account shows especially how the district was influenced by the ice of glacial times, and an excellent series of illustrations has been included, most of which were hitherto unpublished. The map of Clew Bay and its numerous partially-drowned drumlins will interest those who have entered Boston harbour from the sea. The large coloured geological map is repeated, by arrangement with the Controller of the Stationery Office, from the Geological Survey memoir.

WE have frequently taken occasion to refute some of the long-lived popular fallacies relating to the weather. The *Scientific American* of October 24 refers to a statement in a recent London weekly journal that "it is one of the extraordinary things of warfare that a big battle invariably produces rain." Our American contemporary has no difficulty in refuting the "particularly fatuous fallacy" that a battle could have any appreciable effect on the temperature or humidity of the air, upon which conditions rainfall depends. He points out that rainfall may follow battles for various reasons, *e.g.* meteorological records in northern France show an average of about 157 rain-days per annum, according to which rain might possibly fall about every other day. Recent literature upon the subject is abundant and conclusive; as one instance we may refer to an interesting and instructive article by Prof. Cleveland Abbe in the United States *Popular Science Monthly* of January, 1911, which shows by laboratory experiments that the firing of cannon or dynamite to produce rain cannot possibly succeed. We may also mention a pertinent communication to *Symons's Meteorological Magazine* of March, 1911, in which Mr. F. Gaster (formerly of the Meteorological Office) pointed out that at Shoeburyness, where great guns are fired almost daily, the average rainfall is probably the smallest in the United Kingdom.

THE Committee of the Institution of Civil Engineers, which has been making inquiries as to the best course of training for engineers, mentions in its report that one firm considered technically trained men of "no use for dividend earning." Mr. F. M. Denton, in a letter in the *Electrician* of November 6, points out that this prejudice against technical collége-trained men on the part of engineering firms has cost us very dearly in the past, much of our best trade, and more new trade we should have liked, having gone to our rivals. The hope of regaining and retaining this trade in the future is, he considers, elusive unless manufacturers are prepared to recognise that a technical training permits a man to see further than he would otherwise do, and that research carried out by such men has been responsible for practically all the advance in heavy electrical engineering in recent years. We cannot as a nation content ourselves with merely making and selling what others have developed, but must provide our own army of research, and lead instead of following.

IN the *Comptes rendus* for November 3 M. G. Lippmann directs attention to the possibility of applying the Hughes induction balance to military surgery. This invention, it is remarked, appears to-day to be totally forgotten. It consists of a battery, two small induction coils, a contact-breaker, and a telephone, the connections being crossed in the primary circuit so that the induced electromotive forces are in contrary directions. The coils can then be adjusted so that no sound is heard in the telephone in the secondary circuit. On the approach of a metallic mass to one of the bobbins, a sound is heard in the telephone. If the metal is magnetic, as is the case with a fragment of shell or a German bullet, the effect is more marked; French and German bullets can in this way be distinguished. M. Lippmann thinks the apparatus should be useful in military surgery, as it is easily made in numbers, simple to use, portable, and cheap.

ALUMINIUM is now employed to a greater or less extent in almost all engineering and allied trades, but it is doubtful if the full extent and variety of its applications are generally recognised. About 60,000 tons of the material are produced every year. *Engineering* for November 13 points out that there is no reason why the foundry of a general engineering shop should not produce aluminium castings in the same way that it now produces those of the copper alloys. Probably the reason for the neglected use of aluminium is that the average engineer is not practised in the manipulation of this metal. A quite definite case can be made out for the employment of aluminium for low-tension electric cables, particularly those of large section. There are a number of important installations in existence, *e.g.* the Paris General Omnibus Company has 650 tons of aluminium cables, yet on the whole the material does not occupy the position which might be expected. There is little doubt that in many cases copper cables are now being installed where important saving might be made by employing aluminium.

OUR ASTRONOMICAL COLUMN.

COMET 1914*d* (LUNT).—The comet discovered by Dr. Lunt at the Cape Observatory is travelling northward, and the elements and ephemeris (the *Observatory*, November) have been calculated by Drs. Hough and Halm, and these are as follows:—

Elements.

T = 1914 August 4·91638 G.M.T.

$$\left.\begin{aligned}\omega &= 269^\circ\ 53'{\cdot}6\\ \Omega &= 0^\circ\ 22'{\cdot}5\\ i &= 77^\circ\ 53'{\cdot}3\end{aligned}\right\}1914{\cdot}0$$

$\log q = 9{\cdot}85024$

Ephemeris for Greenwich Midnight.

	R.A. h. m. s.	Decl. ° ′
Nov. 18	21 51 8	+8 27
22	53 20	9 13
26	55 41	9 56
30	21 58 21	10 38

It is stated that the corrections to the above on October 11 were −20s., +7′, and on October 17 −25s., +11′.

SERIES LINES IN SPARK SPECTRA.—In the issue of this journal for April 9 of the present year (vol. xciii., p. 145) a summary was given of the Bakerian lecture delivered by Prof. Fowler on April 2 on series lines in spark spectra. Attention is directed to the fact that this lecture is now published in the *Philosophical Transactions* of the Royal Society (Series A, vol. ccxiv., pp. 225–66), and is accompanied by some excellent reproductions from photographs of the spectrum of the magnesium arc *in vacuo*, the various series of arc and enhanced lines being clearly indicated.

A BRILLIANT FIREBALL.—Mr. W. F. Denning writes: "On November 11, at 11.13 p.m., a magnificent meteor was seen from near Purley, Surrey, Stowmarket, Hornsey, and other places. It looked like an unusually large ball from a Roman candle firework, and moved very slowly in the north-east sky, occupying about 6 sec. in an extended course. It was not a Leonid, but apparently from a radiant near α Lyræ in the north-west. The meteor illumined the sky vividly for several seconds, and was evidently rather near the earth's surface. From a preliminary discussion of the few descriptions already to hand it appears that the object fell from a height of fifty to thirty-two miles, and its velocity was about eleven miles a second. There is no known shower near Vega at the middle of November, but certain large meteors appear to be isolated. Some of the observers supposed it to have been one of the regular November meteors, but its direction was different and its speed altogether too slow for it to have been a Leonid."

MEASURED PARALLAXES SUMMARISED.—A reprint from the *Astronomische Nachrichten*, No. 4754, has been received, and it contains a communication on measured parallaxes summarised by Mr. O. R. Walkey. The author states that in view of the inherent uncertainty of all measured parallaxes, it does not seem profitable to enter into a detailed discussion of the individual results, but instead the results are summarised in a series of tables of distance and consequent luminosities and cross-motions speeds according to the spectral type. The tables given represent 521 stellar systems, not counting the sun. The first three tables do not include the Hyades group, which consists mainly of first-type stars; these are dealt with in a fourth table according to their component spectral classes. The investigation is one that is the result of a large amount of labour, and the essence of the work lies in the tables, which will no doubt be carefully scrutinised by those to whom the subject is of special interest.

REPORT OF THE PARIS OBSERVATORY FOR 1913.—Like all other large observatories situated in or near towns, the work of the Paris Observatory is being severely handicapped by the presence of disadvantageous observing conditions such as smoke, night glare, etc. The report for the year 1913 gives a good idea of the great number of branches of work undertaken, but in the different summaries of the recent progress there is an underlying tone of regret that much cannot be done and much that is done is not as satisfactory as it might have been owing to the present observing conditions. Monsieur Baillaud, the director, opens his report with a reference to the deplorable conditions of the actual situation and to the indispensability of the creation of a branch establishment which he advocated two years ago. With regard to the meridian work, the north and south horizons have been shut out by seven-storey buildings, and he points out how the work of the equatorials is restricted by the haze and fog in the lower strata of the atmosphere of Paris. Comet Delavan was estimated as of the eleventh magnitude at Besançon. Bordeaux, and Lyon, while at Paris it appeared of magnitude 13. Regular photometric work, so important for the undertaking of the Carte du Ciel, is described as impossible, and in the astrophysical department the quality of the stellar images projected on the slit exercises unfortunately a very great influence on the determinations of radial velocity. Numerous other references to other branches of work effected are given, making a clear case for the necessity for an out-station. For the present, no steps can be taken, but it is hoped that in the near future Monsieur Baillaud's appeal will be considered and carried out. The annual report takes the same form as in previous years, and the work of the several departments during the past year is described in the various sections.

THE FUNCTION OF THE EARTH IN RADIO-TELEGRAPHY.

A LECTURE on the above subject was delivered on Friday evening, November 13, by Dr. J. A. Fleming, to the members of the Wireless Society of London, at the Institution of Electrical Engineers. Dr. Fleming said that the present period of enforced inactivity for all loyal radio-telegraphists, except those engaged at the seat of war, offered an opportunity to re-consider some of the purely scientific questions involved in the art. He proposed therefore to discuss the function of the earth in radio-telegraphy. Apart from the disputed question whether the aerial wires should preferably be earthed at the base or connected to an insulated balancing capacity, it was well known that the nature of the soil or surface between the transmitting and receiving stations had a great effect on the signal strength. This effect depended much upon the wave-length. Thus Dr. L. W. Austin had shown that the ground to the north and north-east of Newport, Rhode Island, U.S.A., exercised a powerful absorption on radio-telegraphic waves of about 1000 metres wave-length. Experiments made between Brant Rock wireless station and a U.S. cruiser *Birmingham*, lying at Newport, showed that whereas electric waves of 3750 metres wave-length suffered little or no absorption in travelling over the 45 miles other than that due to the normal space decrease of energy, waves 1000 metres in length lost 95 per cent. of their signalling energy in passing over the same district.

Dr. Fleming first gave a brief mathematical discussion showing the manner in which the gradual penetration of an alternating current into a conductor can be explained. It is well known that high frequency electric currents are confined to a thin skin or layer of the surface of metallic wires. In the case of copper this skin has a thickness of about 0·25 mm. for currents of a frequency of one million. In the case of iron the skin for the same frequency is about 0·02 mm.

An elegant experiment was shown by Dr. Fleming with his cymometer to illustrate this surface flow of high-frequency currents. An oscillation circuit was arranged in which high-frequency currents were generated, and these were detected by placing alongside a cymometer having a Neon vacuum tube as a detector of secondary oscillations in its circuit. In the primary oscillation circuit were inserted successively small spirals of copper, brass, iron, and galvanised iron; all having the same size and same number of turns. The oscillations in the cymometer circuit were indicated by the brilliant glow of the Neon tube. When the iron spiral was inserted the Neon tube did not glow, because of the damping of the oscillations caused by the energy absorbed to magnetise the iron.
